**ABSTRACT** The existing authentication schemes in wireless sensor networks (WSNs) are mostly used in single-gateway mode. With the wide deployment of WSNs, the drawbacks of single-gateway mode are gradually becoming more noticeable. In traditional single-gateway WSNs, high-speed data streams are prone to conflict during data aggregation, which may reduce the performance of the network. Most of the existing multi-gateway schemes are based on lightweight operations such as hash functions, exclusive OR (XOR), and symmetric encryption algorithms, which cannot achieve forward secrecy. In this paper, we propose a lightweight multi-gateway authentication scheme based on the Rabin cryptosystem. Since Rabin only requires a module-square operation for encryption, its computational overhead is relatively low. Therefore, the encryption operation is usually used on the sensor side with resource constraints to save resources. In addition, Scyther is used to prove the security of the proposed scheme. The analysis shows that the proposed scheme can achieve higher security with lower computational overhead.

**INDEX TERMS** Wireless sensor networks, authentication, multi-gateway, rabin cryptosystem.

#### I. INTRODUCTION

Wireless Sensor Networks (WSNs), as one of the core technologies of the perception layer of the Internet of Things (IoT), consist mostly of terminal devices with limited resources. Due to the simple structure and low computing power of WSNs, ensuring their access security has been an important research direction for IoT security. Insecure terminal devices will pose a threat to the security of the whole network. EI-Haij et al. [1] pointed out that a single compromised node can be turned into a malicious one that can bring down the whole system or cause disasters. Atzori et al. [2] pointed out that authentication is a key issue in IoT security, and it is essential for network security to verify the identities of the entities accessing the IoT. In traditional single-gateway authentication schemes, high-speed data streams are prone to conflict during data aggregation.

The associate editor coordinating the review of this manuscript and approving it for publication was Marco Martalo<sup>(D)</sup>.

When edge sensors are too far away from gateway nodes, it will lead to increased communication costs and reduced network performance. Therefore, it is of great significance to study the multi-gateway authentication protocol for WSNs.

#### A. LITERATURE REVIEW

This paper mainly classifies the current mainstream authentication protocols into two kinds: single-gateway protocols and multi-gateway protocols.

In 1981, Lamport [3] first proposed a single-factor authentication protocol based on password. In 2004, Watro et al. [4] proposed a user authentication protocol using RSA and Diffie-Hellman algorithms that placed the computationally expensive operations on parties external to WSNs. However, Das [5] pointed out that Watro et al.'s protocol suffered from impersonation attack. In 2006, Wong et al. [6] proposed a dynamic strong password solution to access control in WSNs, which only required simple hash function and XOR operations. However, in 2007, Tseng et al. [7] showed that

Wong et al.'s scheme was vulnerable to replay attack and forgery attack, then proposed a lightweight dynamic user authentication scheme for WSNs, which was in possession of many advantages, including resistance to replay attack and forgery attack. Since many schemes relied only on password security, they were vulnerable to off-line password guessing attack. To avoid these problems, two-factor authentication protocols based on password and smart card have been proposed one after another. In 2009, Das [5] established a novel two-factor authentication scheme, where the user is in possession of a password and a smart card. In the same year, Nyang and Lee [8] pointed out that Das's protocol [5] was vulnerable to off-line password guessing attack, and presented a countermeasure to overcome this drawback. In 2010, Chen and Shih [9] showed Das's scheme [5] failed to achieve mutual authentication, and they proposed a robust mutual authentication protocol. In 2010, Cheikhrouhou et al. [10] proposed a lightweight authentication scheme based on the symmetric algorithm AES, in which mutual authentication and key establishment mechanisms were used to ensure the confidentiality and data integrity of the protocol. Public key algorithmbased schemes can accomplish more security attributes than symmetric algorithm-based schemes, but they also use up more system resources. In 2011, Yeh et al. [11] found that Chen and Shih's scheme [9] failed to provide a secure method for updating user passwords and was vulnerable to the insider attack, where the privileged insider can obtain the user's password. To address these existing issues, they first applied the elliptic curve cryptography (ECC) algorithm and smart card to construct WSNs authentication protocol. Han [12] pointed out that the above protocol cannot provide perfect forward secrecy and cannot achieve mutual authentication or key agreement between user and sensor nodes. In 2013, Shi and Gong [13] established an authentication protocol to achieve perfect forward secrecy, mutual authentication, and key agreement between user and sensor nodes. Choi et al. [14] pointed out that Shi and Gong's protocol [13] was vulnerable to session key attack, stolen smart card attack, and node energy consumption attack, and improved on these drawbacks. Authentication protocols based on ECC are one of the methods used in authentication protocols in order to improve the security and privacy of RFID systems. In 2016, Dinarvand and Barati [15] examined and compared protocols that utilized this method to establish security. In 2019, a RFID authentication protocol wad presented using ECC for mutual authentication overcome weakness of the existing schemes by Dinarvand and Barati [16]. In 2020, Srinivas et al. [17] came up with a novel user authentication scheme for secure authentication of medical data using Rabin, which could achieve mutual authentication between a user and a wearable sensor node and establish a secret key that is used for future secure communications. In 2021, Wang et al. [18] utilized the ECC to propose an enhanced anonymous authentication scheme for a smart healthcare system. In 2022, Hayouni [19] presented a lightweight authentication protocol for IoT-based

WSNs to provide mutual authentication services for connected objects. In 2022, Nezhad et al. [20] proposed a secure routing method to prevent the intrusion of malicious nodes, consisting of star structure, key distribution, and intra-cluster communication. Hossein et al. [21] proposed a three-factor authentication scheme based on the blockchain platform for the IoT environment.

Amin and Biwas [22] first proposed a two-factor based multi-gateway authentication and key agreement protocol for WSNs that was able to ensure user anonymity while resisting password guessing attack, insider attack, stolen verifier attack, etc in. In the same year, Das et al. [23] pointed out that Amin and Biwas's scheme could not protect user anonymity. Additionally, it was vulnerable to password guessing attack, stolen smart card attack and identity guessing attack. After that, Das et al. proposed a three-factor authentication protocol based on the AES algorithm to solve these problems. However, Wu et al. [24] pointed out that the scheme in [23] also failed to resist the tracking attack and did not have a common session key for three parties. Gou et al. [25] found that the two-factor authentication scheme in [24] could not resist offline password guessing attack and identity guessing attack. In addition, the protocol in [24] was vulnerable to internal privilege attack, user tracing attack and sensor forgery attack. To address the security issues in Wu et al.'s protocol [24], Gou et al. [25] proposed a three-factor authentication protocol for multi-gateway WSNs. In 2017, Srinivas et al. [26] analyzed Amin and Biwas's scheme [22] in details and proposed an improved three-factor authentication protocol. Wang et al. [27] found that Srinivas et al.'s scheme [26] still suffered from smart card stolen attack, node capture attack, and tracking attack and could not guarantee forward secrecy. In 2019, Lee et al. [28] proposed a three-factor mutual authentication for multi-gateway protocols, in which they needed to register at all gateway nodes if users hoped to use all sensor nodes. In 2022, Dai and Xu [29] found the scheme in [25] was prone to single point of failure, and they proposed a novel elliptic curve cryptograph based three-factor authentication scheme for multi-gateway WSNs that realized smart card revocation, dynamic sensor node addition, and could withstand single point of failure. Zhao et al. [30] presented a novel three-factor authentication and key agreement protocol based on elliptic curve cryptography for IIoT environments, where their scheme can be used in single-gateway environments and can be extended to multi-gateway environments. In 2023, Chen et al. [31] proposed a two-factor multi-gateway authentication protocol based on password and smart card that could resist the joint password and identity guessing with the smart card loss attack.

A majority of schemes leverage ECC operations to ensure they can achieve more security attributes. However, ECC provides more security while producing more overhead. The Rabin mechanism is characterized by its property of computational asymmetry. The encryption performs a modular squaring operation, while the decryption performs a module-square root operation. Rabin's encryption is significantly less than the ECC point multiple, which is the motivation that the proposed scheme leverages Rabin to build.

# **B. OUR CONTRIBUTIONS**

1. We proposed a new three-factor user authentication and key agreement scheme using Rabin [32] for multi-gateway WSNs. Due to the lightweight computation of Rabin, it is suitable for devices with limited computational resources, such as sensor nodes. The proposed single-gateway and multi-gateway authentication schemes can also protect user privacy and achieve good forward secrecy due to the introduction of a public key system.

2. The designed authentication protocol is demonstrated to be secure using the random oracle model (ROM) [33]. As a result, the lightweight authentication scheme is secure against the Dolev-Yao adversary model.

3. Scyther [34], a verification tool, is utilized to simulate the security of the proposed protocols, and the results show that our protocols can achieve mutual authentication and can resist many attacks.

#### C. ORGANIZATION OF THE PAPER

The remaining sections are organized as follows: In Section II, we present the preliminary information, including the description of Rabin, the network model, and the threat model. In Section III, we propose a novel three-factor authentication and key agreement scheme for single-gateway and multi-gateway WSNs, respectively. In Section IV, we describe formal and informal security analysis and provable security. In Section V, we compare the security and efficiency of our scheme with those of related schemes. Finally, we summarize this article in Section VI.

# **II. PRELIMINARIES**

#### A. RABIN

In 1979, Rabin [32] proposed a novel public-key cryptography mechanism. Selecting two different large primes p and q that satisfy  $p \equiv q \equiv 3 \mod 4$  as the private key and computing N = pq as the public key. The user stores the private key and discloses the public key. Using a public key N to encrypt the message m can obtain ciphertext c,  $c = m^2 \mod N$ . Decryption necessitates the use of the private keys p, q to determine  $c \mod p$  and  $c \mod q$ , respectively. Subsequently, utilizing the Chinese remainder theorem (CRT), only the legitimate user in possession of the private key can calculate the decryption consequences.

The security of the Rabin cryptography mechanism is based on the intractable integer factorization problem. Since the intractable integer factorization problem (IFP) is considered computationally difficult under certain conditions, Rabin can be considered secure. In addition, Rabin is a typical asymmetric algorithm, and its encryption and decryption operations have different computational overheads. Rabin's encryption operations are lightweight, but the decryption operations consume a significant amount of resources. Therefore, encryption operations are usually performed on the side of sensor nodes with limited resources, and decryption operations can be performed on the side of gateway nodes with strong computing power.

# B. NETWORK MODEL

According to literature [22], [24], [26], the network model used in the home region is a standard model for a singlegateway environment and consists of three types of entities: user nodes, gateway nodes, and sensor nodes, as shown in Figure 1. In this architecture, three types of entities can authenticate each other through two complete rounds of information interaction, which can be extended to a multi-gateway architecture. WSNs are typically unattended networks that cannot be physically changed on a large scale once they have been deployed. Due to the limited memory and computing power of sensor nodes, it is a great burden for edge sensors and gateway nodes to receive and send messages when the network size is too large or the distance is too long. Therefore, more gateways need to be extended to increase the network's capacity. Figure 2 shows us a multi-gateway architecture. In steps 1-4, the Home Gateway Node (HGWN) helps to establish the trust connection between the user and the Foreign Gateway Node (FGWN), and in steps 5-8, the user accesses the sensor via the FGWN.

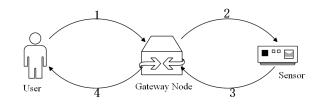

FIGURE 1. Network model of HGWN.

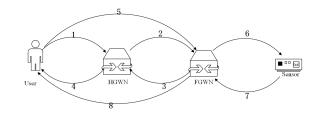

FIGURE 2. Network model of FGWN.

#### C. THREAT MODEL

Dolev-Yao threat model [35] is often used to formally analyze authentication protocols in communication networks, where the model assumes that two communication entities communicate over an insecure channel. WSNs can adopt a similar threat model where the channel is insecure and the terminal points cannot be generally trusted. Dolev-Yao threat model defines the precise mathematical model, and the basic assumptions listed are as follows:

#### 1. In a perfect public key system:

a. The one-way hash functions used are unbreakable.

b. The public directory is secure and cannot be tampered with.

2. We will assume the following about an adversary  $\mathscr{A}$ :

a. An adversary can obtain any message passing through the network.

b. An adversary can be a legitimate user of a network and, in particular, can initiate a conversation with any other user.

c. An adversary will be able to act as a receiver for any sender.

### **III. PROPOSED SCHEME**

Our designed protocol is divided into seven phases: initialization phase, user registration phase, sensor registration phase, user login phase, authentication and key agreement in *HGWN*, authentication and key agreement in *FGWN*, and user key update.

## A. INITIALIZATION PHASE

During the initialization phase, *SA* selects the identity  $SID_j$ for each sensor, sharing this global devices list with all gateways. After that, *SA* selects two different large random numbers  $p_h$ ,  $q_h$  for home gateway node (*HGWN*),  $p_h \equiv q_h \equiv$ 3 mod 4 ( $p_h$ ,  $q_h$  are congruent with module 4) and computes the public key  $N_h = p_h q_h$ . In the same way as above, the foreign gateway node (*FGWN*) gets a pair of private keys, which are two different large prime numbers  $p_f$ ,  $q_f$ , where  $p_f \equiv q_f \equiv 3 \mod 4$  ( $p_f$ ,  $q_f$  are congruent with module 4). *FGWN* computes the public key  $N_f = p_f q_f$ . Finally, two cryptographic collision-resistant one-way hash functions  $h_1(\cdot) : \{0, 1\}^* \rightarrow \{0, 1\}^l$  and  $h_2(\cdot) : \{0, 1\}^* \rightarrow \{0, 1\}^*$  are selected, where *l* is the output length of hash function. Table 1 shows the symbols used in this paper.

#### **B. USER REGISTRATION PHASE**

Biometric features are added in this scheme to improve the security of the system and can be well used in the setting of an authentication scheme because of their uniqueness. Compared with low-entropy passwords, biometric features also have the advantages of being difficult to forge and share and not being easy to lose. Figure 3 illustrates the registration procedure.

**Step1**:  $U_i$  inputs his/her own identity  $ID_i$ , password  $PW_i$ and the biometric information  $BIO_i$ . After that, the fuzzy extractor computes biometric key data  $\sigma_i$  and common parameter  $\theta_i$  using  $Gen(BIO_i) \rightarrow (\sigma_i, \theta_i)$ . The common parameter  $\theta_i$ is stored in  $SC_i$ . Next,  $U_i$  computes  $HID_i = h_1(ID_i||\sigma_i)$  and  $HPW_i = h_1(PW_i||\sigma_i)$ , and transmits  $\{HID_i, HPW_i\}$  to HGWNover a secure connection.

**Step2**: After getting the messages  $HID_i$  and  $HPW_i$  from  $U_i$ , HGWN creates a random number  $r_h$ , and computes  $A_i = h_1(HID_i||p_h||q_h||r_h) \oplus HID_i$ ,  $B_i = h_1(HID_i||r_h||HPW_i)$ , and  $C_i = HID_i \oplus r_h$ . The long-term secret  $\{HID_i, r_h\}$  is stored in HGWN's memory. HGWN delivers a message  $\{A_i, B_i, C_i\}$  to  $U_i$  over a secure connection.

#### TABLE 1. Symbol description.

Symbol	Description
SA	i-th user node
$SN_i$	j-th sensor node
$SC_i$	Smart card of $U_i$
HGWN	Home gateway node
FGWN	Foreign gateway node
$ID_i$	Identity of $U_i$
SIDi	Identity of $SN_i$
$ID_{hg}$	Identity of <i>HGWN</i> : $\{0, 1\}^l$
$ID_{fg}$	Identity of FGWN: $\{0, 1\}^l$
$PW_i$	Password of $U_i$
BIOi	Biometric information of $U_i$
$p_u, q_u$	Large secret prime numbers for certain User
$p_h, q_h$	Large secret prime numbers for <i>HGWN</i>
$p_f, q_f$	Large secret prime numbers for <i>FGWN</i>
$N_u$	Public key of certain User $N_u = p_u q_u$
$N_h$	Public key of the HGWN $N_h = p_h q_h$
$N_f$	Public key of the FGWN $N_f = p_f q_f$
$r_u, r_h, r_{hq} r_s, r_f, r_{fn}$	Random numbers: $\{0, 1\}^l$
$T_1, T_2,, T_8$	Timestamps
$\Delta T$	Acceptable maximum transmission delay
SK	Session key
$h_1(\cdot)$	One-way hash function: $\{0,1\}^* \rightarrow \{0,1\}^l$
$h_2(\cdot)$	$\begin{cases} (0,1) \rightarrow (0,1) \\ \text{One-way hash function:} \\ \{0,1\}^* \rightarrow \{0,1\}^* \end{cases}$
⊕ ⊕	Exclusive-or operation
	Concatenation operation

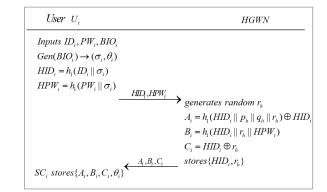

FIGURE 3. User registration phase.

**Step3**: After receiving the message  $\{A_i, B_i, C_i\}$ , long-term secret  $\{A_i, B_i, C_i, \theta_i\}$  is preserved in  $U_i$ 's  $SC_i$ .

#### C. SENSOR REGISTRATION PHASE

Each sensor node is given a distinct identity by SA. In order to register,  $SN_j$  transmits its own identity  $SID_j$  to the nearby HGWN over a secure channel. The registration procedure is described in Figure 4.

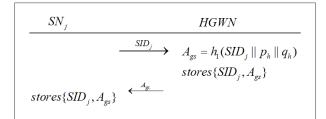

FIGURE 4. Sensor registration phase.

**Step1**:  $SN_j$  utilizes a secure connection to convey its own identity  $SID_j$  to the nearest *HGWN*.

**Step2**: After receiving the message from  $SN_j$ , *HGWN* computes  $A_{gs} = h_1(SID_j||p_h||q_h)$  and maintains the long-term secret { $SID_j$ ,  $A_{gs}$ } in its memory. Then *HGWN* transmits message  $A_{gs}$  to  $SN_j$  over a secure connection.

**Step3**: When  $SN_j$  receives the message  $A_{gs}$ ,  $SN_j$  preserves the long-term secret { $SID_j$ ,  $A_{gs}$ } in its own memory.

#### D. USER LOGIN PHASE

Before  $U_i$  enters his/her identity  $ID_i$ , password  $PW_i$ , and biometric information  $BIO_i$ ,  $U_i$  inserts his/her smart card  $SC_i$ into a terminal. Next, the terminal utilizes a fuzzy extractor to recover the biometric key data  $\sigma_i$ , that is  $Rep(BIO_i, \theta_i) \rightarrow \sigma_i$ . After that, the terminal figures out  $HID_i = h_1(ID_i||\sigma_i)$  and  $HPW_i = h_1(PW_i||\sigma_i)$ , and reads the secret parameters stored in its memory, computing  $r_h^* = HID_i \oplus C_i$  and  $B_i^* = h_1(HID_i||r_h^*||HPW_i)$ . The terminal verifies  $B_i^* \stackrel{?}{=} B_i$ . When the verification is successful,  $U_i$  is able to log in. Otherwise, the login request will be rejected and no further procedure will be carried out.

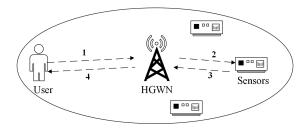

$U_i$	Terminal
Inserts smart card $SC_i$	to a terminal
Inputs ID <sub>1</sub> , PW <sub>1</sub> , BIO <sub>1</sub>	
	computes $Rep(BIO_i, \theta_i) \rightarrow \sigma_i$
	$HID_i = h_1(ID_i    \sigma_i)$
	$HPW_i = h_1(PW_i \parallel \sigma_i)$
	$r_h^* = HID_i \oplus C_i$
	$B_i^* = h_1(HID_i \parallel r_h^* \parallel HPW_i)$
	If $B_i^* \neq B_i$ abort
	generates random $r_u$ , tampstamp $T_1$ , $N_u = p_u \cdot q$
	computes $A_h = A_i \oplus HID_i$
	$M_1 = (HID_i    ID_{hg}    SID_j    N_u    r_u    r_h^*)^2 \mod N_1$
	$M_2 = h_1(HID_i    r_u    A_h    N_u    M_1    T_1)$

FIGURE 5. User login phase.

If user login is successful, generating a random number  $r_u$ , timestamp  $T_1$ , two large prime numbers  $p_u$ ,  $q_u$  and public key  $N_u = p_u \cdot q_u$ , user calculates  $A_h = A_i \oplus$  $HID_i$ ,  $M_1 = (HID_i||ID_{hg}||SID_j||N_u||r_u||r_h^*)^2 \mod N_h$  and  $M_2 = h_1(HID_i||r_u||A_h||N_u||M_1||T_1)$ . Figure 5 demonstrates the entire procedure.

# E. AUTHENTICATION AND KEY AGREEMENT PHASE IN HGWN

When  $U_i$  requires access to the  $SN_j$  in the home region where the  $SN_j$ 's identity is in the registered devices database of *HGWN*, no foreign gateway is required. The mutual authentication between  $U_i$  and  $SN_j$  and the establishment of session keys can be performed through the *HGWN* only. The network model of the system is shown in Figure 6.

#### FIGURE 6. HGWN model.

Next, the authentication and key agreement phase in HGWN is described in the following steps, as shown in Figure 7.

**Step1**:  $U_i$  forwards the message { $M_1, M_2, T_1$ } to the closest *HGWN*.

**Step2**: When *HGWN* receives the message from  $U_i$ , *HGWN* obtains the current timestamp  $T_1^*$  and verifies  $T_1$ 's validity, i.e.,  $|T_1^* - T_1| < \Delta T$ . HGWN will refuse the current session if the timestamp  $T_1$  is out of date. Otherwise, HGWN decrypts  $M_1$  with its own private keys  $p_h, q_h$  and then obtains  $HID_i, ID_{hg}, SID_j, N_u, r_u, r_h^*$ . Then HGWN checks whether  $r_h^*$  is equal to  $r_h$  preserved in its own memory. If  $r_h^* = r_h$ , then it performs subsequent calculations, otherwise, it aborts the current session. HGWN computes  $A_h^* = h_1(HID_i||p_h||q_h||r_h^*)$  and  $M_2^* =$  $h_1(HID_i||r_u||A_h^*||N_u||M_1||T_1)$  and verifies whether  $M_2^*$  is equal to the received  $M_2$ . If  $M_2^* \neq M_2$ , the current session is terminated. Otherwise, HGWN creates a random number  $r_{hg}$ , a new timestamp  $T_2$ , and computes  $A_{gs} = h_1(SID_i||p_h||q_h)$ ,  $M_3 = (HID_i||r_u||r_{hg}||N_u) \oplus h_2(A_{gs}||T_2||SID_j)$  and  $M_4 =$  $h_1(HID_i||SID_j||r_{hg}||N_u||A_{gs}||T_2)$ . Finally, HGWN transmits the message  $\{M_3, M_4, T_2\}$  to  $SN_i$ .

**Step3**: After receiving the message *HGWN* sent,  $SN_j$ acquires the current timestamp  $T_2^*$  and checks  $T_2$ 's validity, i.e.,  $|T_2^* - T_2| < \Delta T$ . If the timestamp  $T_2$ is out of date,  $SN_j$  rejects the current session. Otherwise,  $SN_j$  computes  $h_2(A_{gs}||T_2||SID_j)$  and calculates  $h_2(A_{gs}||T_2||SID_j) \oplus M_3$  to obtain  $(HID_i||r_u||r_{hg}||N_u)$ .  $SN_j$ computes  $M_4^* = h_1(HID_i||SID_j ||r_{hg}||N_u||A_{gs}||T_2)$  and checks whether  $M_4^*$  is equal to the received  $M_4$ . If  $M_4^* \neq$  $M_4$ ,  $SN_j$  aborts the current session. Otherwise,  $SN_j$  creates a random number  $r_s$ , a new timestamp  $T_3$ , and computes  $M_5 = (HID_i||SID_j||A_{gs}||r_s)^2 \mod N_u$ , SK = $h_1(HID_i||SID_j||r_u||r_s)$ ,  $M_6 = (h_1(SK||A_{gs}))^2 \mod N_h$ ,  $M_7 = h_1(HID_i||SID_j||r_{hg}||A_{gs}||M_5||M_6||T_3)$  and  $M_8 =$  $h_1(HID_i||SID_j||SK||r_u||r_s||M_5)$ . Finally,  $SN_j$  sends the message  $\{M_5, M_6, M_7, M_8, T_3\}$  to HGWN. **Step4**: After receiving the message from  $SN_j$ , HGWN first obtains the current timestamp  $T_3^*$  and checks  $T_3$ 's validity, i.e.,  $|T_3^* - T_3| < \Delta T$ . HGWN cancels the current session if the timestamp  $T_3$  is not current. Otherwise, HGWN computes  $M_7^* = h_1(HID_i||SID_j||r_{hg}||A_{gs}||M_5||M_6||T_3)$ , and inspects  $M_7^* \stackrel{?}{=} M_7$ . If  $M_7^* \neq M_7$ , the current session is terminated by HGWN. Otherwise, HGWN creates a new timestamp  $T_4$  and figures out  $M_9 = h_1(M_5||M_8||r_u||A_h||T_4)$ , and finally sends the message { $M_5, M_8, M_9, T_4$ } to  $U_i$ .

**Step5**: After getting the message from *HGWN*,  $U_i$  first acquires the current timestamp  $T_4^*$  and confirms  $T_4$ 's validity, i.e.,  $|T_4^* - T_4| < \Delta T$ . If the timestamp  $T_4$  is not fresh,  $U_i$  aborts the current session. Otherwise,  $U_i$  calculates  $M_9^* = h_1(M_5||M_8||r_u||A_h||T_4)$  and verifies whether  $M_9^*$  is equal to the received  $M_9$ . If  $M_9^* \neq M_9$ ,  $U_i$  rejects the current session. Otherwise,  $U_i$  decrypts  $M_5$  with its own private keys  $p_u$ ,  $q_u$  and then obtains  $HID_i$ ,  $SID_j$ ,  $A_{gs}$ ,  $r_s$  and calculates  $SK^* = h_1(HID_i||SID_j||r_u||r_s)$  and  $M_8^* = h_1(HID_i||SID_j||SK^*||r_u||r_s||M_5)$ , and inspects whether  $M_8^*$  is equal to the received  $M_8$ . If  $M_8^* \neq M_8$ , the current session is rejected by  $U_i$ . Otherwise,  $U_i$  calculates  $M_6^* = h_1(SK^*||A_{gs})$  and sends  $M_6^*$  to *HGWN*.

**Step6**: *HGWN* decrypts  $M_6$  using its own private keys  $p_h$ ,  $q_h$  to obtain  $h_1(SK||A_{gs})$ . *HGWN* checks  $M_6^* \stackrel{?}{=} h_1$  (*SK* ||*A*<sub>gs</sub>). If  $M_6^* \neq h_1(SK||A_{gs})$ , *HGWN* aborts the current session. Otherwise, the authentication is successful.  $U_i$  and *SN<sub>j</sub>* share a session key *SK*.

# F. AUTHENTICATION AND KEY AGREEMENT PHASE IN FGWN

If  $U_i$  needs access to  $SN_j$  in the foreign region, where  $SID_j$  is not in *HGWN*'s database of registered devices, it is necessary to use a foreign gateway to authenticate between  $U_i$  and  $SN_j$ . In this case, the network model of the system is shown in Figure 8.

The authentication and key agreement phase in FGWN is described in the following steps, as shown in Figure 9 and Figure 10.

**Step1**:  $U_i$  generates the message  $\{M_1, M_2, T_1\}$  as in user login phase, and transmits it to the nearest *HGWN*.

**Step2**: When *HGWN* receives the message from  $U_i$ , *HGWN* acquires the current timestamp  $T_1^*$  and checks  $T_1$ 's availability, i.e.,  $|T_1^* - T_1| < \Delta T$ . If the timestamp  $T_1$  is not fresh, *HGWN* aborts the current session. Otherwise, *HGWN* decrypts  $M_1$  with its own private keys  $p_h$ ,  $q_h$  and then obtains *HID<sub>i</sub>*, *ID<sub>hg</sub>*, *SID<sub>j</sub>*,  $N_u$ ,  $r_u$ ,  $r_h^*$ . Then *HGWN* verifies whether  $r_h^*$  is equal to  $r_h$  in its own memory. If  $r_h^* = r_h$ , then it performs subsequent calculations, otherwise, it aborts the current session. *HGWN* computes  $A_h^* = h_1(HID_i||p_h||q_h||r_h^*)$  and  $M_2^* = h_1(HID_i||r_u||A_h^*||N_u||M_1||T_1)$ , and verifies whether  $M_2^*$  is equal to the received  $M_2$ . If  $M_2^* \neq M_2$ , *HGWN* terminates the current session. In WSNs, *HGWN* broadcasts the destination sensor identity *SID<sub>j</sub>* to the remaining gateway nodes. If any *FGWN* detects *SID<sub>j</sub>* in its database, it will respond to *HGWN*. At this point, the *FGWN* generates a random number  $r_{fn}$  and computes  $M_3 = (SID_j||N_f||r_{fn})^2 \mod N_h$ , where  $N_h$  is the public key of the *HGWN*. *FGWN* sends  $M_3$  as the reaction to the *HGWN*. Then *HGWN* will contact this *FGWN* in the following steps. *HGWN* decrypts  $M_3$  using its own private keys and obtains  $SID_j$ ,  $N_f$ ,  $r_{fn}$ . *HGWN* creates a new timestamp  $T_2$  and calculates  $M_4 = (HID_i||SID_j||A_h||r_h||T_2)^2 \mod N_f$ , where  $N_f$  is the public key of the above *FGWN*. *HGWN* computes  $M_5 = h_1(HID_i||r_h||A_h||M_4||r_{fn}||T_2)$  In the end, *HGWN* sends the message  $\{M_4, M_5\}$  to *FGWN*.

**Step3**: After acquiring the message from *HGWN*, *FGWN* decrypts  $M_4$  with its own private keys  $p_f$ ,  $q_f$  to obtain  $HID_i$ ,  $SID_j$ ,  $A_h$ ,  $r_h$ ,  $T_2$ . *FGWN* gets the current timestamp  $T_2^*$  and checks  $T_2$ 's validity, i.e.,  $|T_2^* - T_2| < \Delta T$ . The current session is rejected by *FGWN* if the timestamp  $T_2$  is out of date. Otherwise, *FGWN* figures out  $M_5^* = h_1(HID_i||r_h||A_h||M_4||r_{fn}||T_2)$ , and checks whether  $M_5^*$  is equal to the received  $M_5$ . If  $M_5^* \neq M_5$ , *FGWN* aborts the current session. Otherwise, *FGWN* constructs a random number  $r_f$  and a new timestamp  $T_3$ . After that, *FGWN* computes  $A_f = h_1(HID_i||p_f||q_f||r_f)$ ,  $M_6 = (HID_i||ID_{fg}||A_f||r_f||r_f||r_3)^2 \mod N_h$ . Finally, *FGWN* computes  $M_7 = h_1(HID_i||A_f||M_6||r_f||r_h||T_3)$  and then sends the message  $\{M_6, M_7\}$  to *HGWN*.

**Step4**: After receiving the message from *FGWN*, *HGWN* decrypts  $M_6$  with its own private keys  $p_h$ ,  $q_h$  to obtain  $HID_i$ ,  $ID_{fg}$ ,  $A_f$ ,  $r_h$ ,  $r_f$ ,  $T_3$ . *HGWN* obtains the current timestamp  $T_3^*$  and checks  $T_3$ 's validity, i.e.,  $|T_3^* - T_3| < \Delta T$ . If the timestamp  $T_3$  is not fresh, *HGWN* aborts the current session. *HGWN* checks whether  $r_h^*$  is equal to the received  $r_h$ . If  $r_h^* = r_h$ , then it performs the subsequent calculations, otherwise, it aborts the current session. *HGWN* computes  $M_7^* = h_1(HID_i||A_f||M_6||r_f||r_h||T_3)$  and verifies whether  $M_7^*$  is equal to the received  $M_7$ . If  $M_7^* \neq M_7$ , *HGWN* aborts the current session. Otherwise, HGWN generates a new timestamp  $T_4$  and computes  $M_8 = A_f \oplus A_h$ ,  $M_9 = h_1(HID_i||SID_j||M_8||A_f||T_4)$  and  $R_1 = h_1(SID_j||HID_i||A_h||A_f||T_4) \oplus r_f$ . Finally, *HGWN* sends the message  $\{M_8, M_9, T_4, R_1\}$  to  $U_i$ .

**Step5**: When  $U_i$  receives the message *HGWN* transmitted,  $U_i$  first obtains the current timestamp  $T_4^*$  and verifies  $T_4$ 's validity, i.e.,  $|T_4^* - T_4| < \Delta T$ . If the timestamp  $T_4$  is not fresh,  $U_i$  aborts the current session. Otherwise,  $U_i$  calculates  $A_f^* = M_8 \oplus A_h, r_f^* = R_1 \oplus h_1(SID_j||HID_i||A_h||A_f^*||T_4)$ and  $M_9^* = h_1(HID_i||SID_j||M_8||A_f^*||T_4)$ .  $U_i$  inspects whether  $M_9^*$  is equal to the received  $M_9$ . If  $M_9^* \neq M_9$ ,  $U_i$  aborts the current session. Otherwise,  $U_i$  creates a new random number  $r_u$ , a new timestamp  $T_5$ , and figures out  $M_{10} = (HID_i||SID_j||N_u||r_u||r_f^*)^2 \mod N_f$  and  $M_{11} = h_1(HID_i||r_u||A_f^*||N_u||M_{10}||T_5)$ .  $U_i$  sends message  $\{M_{10}, M_{11}, T_5\}$  to FGWN.

**Step6**: Upon getting the message  $U_i$  sent, *FGWN* acquires the current timestamp  $T_5^*$  and verifies  $T_5$ 's validity, i.e.,  $|T_5^* - T_5| < \Delta T$ . If the timestamp  $T_5$  is not fresh, the current session is terminated by *FGWN*. Otherwise, *FGWN* decrypts  $M_{10}$  with its own private keys  $p_f$ ,  $q_f$ , and then obtains

 $HID_i, ID_{fg}, SID_j, N_u, r_u, r_f^*$ . Then *FGWN* checks whether  $r_f^*$  is equal to  $r_f$  in its own memory. If  $r_f^* = r_f$ , then it performs subsequent calculations. Otherwise, it terminates the

current session. FGWN calculates  $A_f^* = h_1(HID_i||p_f||q_f||r_f^*)$ and  $M_{11}^* = h_1(HID_i||r_u||A_f^*||N_u||M_{10}||T_5)$ . FGWN inspects whether  $M_{11}^*$  is equal to the received  $M_{11}$ .

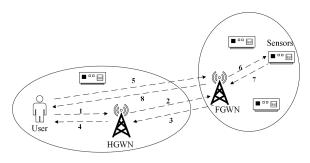

FIGURE 8. FGWN model.

If  $M_{11}^* \neq M_{11}$ , *FGWN* aborts the current session. Otherwise, *FGWN* produces a random number  $r_{fg}$ , a new timestamp  $T_6$ , and computes  $A_{fs} = h_1(SID_j||p_f||q_f)$ ,  $M_{12} = (HID_i||r_u||r_{fg}||N_u) \oplus h_2(A_{fs}||T_6||SID_j)$ , and  $M_{13} = h_1(HID_i||SID_j||r_{fg}||N_u||A_{fs}||T_6)$ . Finally, *FGWN* delivers the message  $\{M_{12}, M_{13}, T_6\}$  to  $SN_j$ .

Step7: After receiving the message FGWN transmitted,  $SN_j$  acquires the current timestamp  $T_6^*$  and checks  $T_6$ 's validity, i.e.,  $|T_6^* - T_6| < \Delta T$ . The current session is refused by  $SN_i$  if the timestamp  $T_6$  is not fresh. Otherwise,  $SN_j$  calculates  $h_2(A_{fs}||T_6||SID_j)$  and calculates  $h_2(A_{fs}||T_6||SID_i) \oplus M_{12}$  to obtain  $(HID_i||r_u||r_{fg}||N_u)$ .  $SN_j$  computes  $M_{13}^* = h_1(HID_i||SID_j||r_{fg}||N_u||A_{fs}||T_6)$ and checks whether  $M_{13}^*$  is equal to the received  $M_{13}$ . If  $M_{13}^* \neq M_{13}$ ,  $SN_i$  aborts the current session. Otherwise,  $SN_j$  creates a random number  $r_s$ , a new timestamp  $T_7$ , and computes  $M_{14} = (HID_i ||SID_j||A_{fs}||r_s)^2 \mod I$  $N_u$ ,  $SK = h_1(HID_i||SID_j||r_u||r_s)$ .  $SN_j$  computes  $M_{15} =$  $(h_1(SK||A_{fs}))^2 \mod N_f, M_{16} = h_1(HID_i||SID_j||r_{fg}||A_{fs}||$  $M_{14}||M_{15}||T_7$  and  $M_{17} = h_1(HID_i||SID_i||SK||r_u||r_s||M_{14})$ . Finally,  $SN_i$  sends the message  $\{M_{14}, M_{15}, M_{16}, M_{17}, T_7\}$  to FGWN.

**Step8**: On receiving the message  $SN_j$  sent, FGWN first gets the current timestamp  $T_7^*$  and inspects  $T_7$ 's validity, i.e.,  $|T_7^* - T_7| < \Delta T$ . If the timestamp  $T_7$  is not fresh, FGWN terminates the current session. Otherwise, FGWN figures out  $M_{16}^* = h_1(HID_i||SID_j||r_{fg} ||A_{fs}||M_{14}||M_{15}||T_7)$ , and inspects whether  $M_{16}^*$  is equal to the received  $M_{16}$ . If  $M_{16}^* \neq M_{16}$ , FGWN rejects the current session. Otherwise, FGWN creates a new timestamp  $T_8$  and computes  $M_{18} = h_1(M_{14}||M_{17}||r_u||A_f||T_8)$ , and finally sends the message  $\{M_{14}, M_{17}, M_{18}, T_8\}$  to  $U_i$ .

**Step9**: When  $U_i$  receives the message *FGWN* transmitted,  $U_i$  first acquires the current timestamp  $T_8^*$  and verifies  $T_8$ 's validity, i.e.,  $|T_8^* - T_8| < \Delta T$ . If the timestamp  $T_8$  is not fresh,  $U_i$  aborts the current session. Otherwise,  $U_i$  calculates  $M_{18}^* = h_1(M_{14}||M_{17}||r_u||A_f||T_8)$ , and verifies whether  $M_{18}^*$  is equal to the received  $M_{18}$ . If  $M_{18}^* \neq M_{18}$ ,  $U_i$  terminates the current session. Otherwise,  $U_i$  decrypts  $M_{14}$  with its own private keys  $p_u$ ,  $q_u$ , and then obtains  $HID_i$ ,  $SID_j$ ,  $A_{fs}$ ,  $r_s$ .  $U_i$  calculates  $SK^* = h_1(HID_i||SID_j||r_u||r_s)$ ,  $M_{17}^* = h_1(HID_i||SID_j$   $||SK^*||r_u||r_s||M_{14})$ , and inspects whether  $M_{17}^*$  is equal to the received  $M_{17}$ . If  $M_{17}^* \neq M_{17}$ ,  $U_i$  refuses the current session. Otherwise,  $U_i$  computes  $M_{15}^* = h_1(SK^*||A_{fs})$  and sends  $M_{15}^*$  to *FGWN*.

**Step10**: *FGWN* decrypts  $M_{15}$  using its own private keys  $p_f$ ,  $q_f$  to obtain  $h_1(SK||A_{fs})$ . *FGWN* checks  $M_{15}^* \stackrel{?}{=} h_1(SK||A_{fs})$ . If  $M_{15}^* \neq h_1(SK||A_{fs})$ , *FGWN* aborts the current session. Otherwise, the authentication is successful.  $U_i$  and  $SN_j$  share a session key *SK*.

#### G. USER PASSWORD UPDATE PHASE

The user password update phase does not need the help of the gateway. When a user needs to update his/her password information, the user needs to input his/her identity  $ID_i$ , old password  $PW_i^{old}$ , and biometric information  $BIO_i$ . Then the terminal regenerates the secret data  $\sigma_i$ , i.e.,  $Rep(BIO_i, \theta_i) \rightarrow \sigma_i$ . After that, the terminal computes  $HID_i = h_1(ID_i||\sigma_i)$  and  $HPW_i^{old} = h_1(PW_i^{old}||\sigma_i)$ , and reads the secret parameters stored in  $SC_i$  to compute  $r_h^* =$  $HID_i \oplus C_i$  and  $B_i^* = h_1(HID_i||r_h^*||HPW_i^{old})$ . The terminal verifies  $B_i^* \stackrel{?}{=} B_i$ . If  $B_i^* = B_i$ ,  $U_i$  login is successful. After that,  $U_i$  inputs his/her new password  $PW_i^{new}$ . The terminal calculates  $HPW_i^{new} = h_1(PW_i^{new}||\sigma_i)$  and updates  $B_i^{new} = h_1(HID_i||r_h||HPW_i^{new})$  stored in  $SC_i$ . Then a password update is completed.

# IV. SECURITY ANALYSIS OF THE PROPOSED SCHEME A. FORMAL VERIFICATION

This subsection focuses on the security of the proposed authentication scheme, utilizing the Dolev-Yao model as the foundation and the Scyther [34] formal analysis tool in order to more comprehensively and systematically assess the security of our proposed scheme. Since the authentication and key agreement phase is the core of this scheme and this phase runs on an insecure wireless public channel, this subsection focuses on the security simulation of the authentication and key agreement.

Figure 11 shows the result of the formal security analysis of the HGWN's authentication and key agreement. Similarly, the analysis of FGWN's result is shown in Figure 12. From the simulation results, it can be seen that the scheme successfully passes the security check of Scyther, which verifies its security and functionality.

#### **B. INFORMAL SECURITY ANALYSIS**

#### 1) MUTUAL AUTHENTICATION

Our scheme ensures mutual authentication between user nodes, gateway nodes, and wireless sensor nodes. In the home region, HGWN verifies  $U_i$  by utilizing  $M_2$ , and  $U_i$  can check the legitimacy of HGWN by relying on  $M_9$ . At the same time,  $SN_j$  and HGWN can achieve mutual authentication using  $M_4, M_7$ .  $U_i$  can check the legitimacy of  $SN_j$  utilizing  $M_8$ . HGWN uses  $M_6$  to help  $SN_j$  check the legitimacy of  $U_i$  and confirm the shared SK.

There is a identical procedure in the foreign region.  $U_i$  and *HGWN* can achieve mutual authentication by relying on  $M_2$ ,  $M_9$ . *HGWN* and *FGWN* can achieve mutual

FIGURE 12. Formal verification result in FGWN.

#### 2) SESSION KEY AGREEMENT

In the home region,  $U_i$  and  $SN_j$  establish a same symmetric session key  $SK = h_1(HID_i||SID_j||r_u||r_s)$  with the help of *HGWN*. In the foreign region, a similar symmetric session key *SK* is shared with the help of *HGWN* and *FGWN*.

#### 3) USER ANONYMITY AND UNTRACEABILITY

In our authentication scheme,  $\mathscr{A}$  cannot access the true identity  $ID_i$  through the transmitted messages. Only the authorized gateway node in possession of private keys  $p_h$ ,  $q_h$ is able to decrypt  $M_1$  to obtain  $U_i$ 's pseudo-identity  $HID_i$ . Similarly,  $\mathscr{A}$  who does not know  $U_i$ 's private keys  $p_u$ ,  $q_u$ and  $SID_j$ 's secret parameter  $A_{gs}$  cannot decrypt  $M_5$  and  $M_3$ . Because of the one-way nature of hash function,  $\mathscr{A}$  cannot obtain  $U_i$ 's pseudo-identity  $HID_i$  from  $M_2$ ,  $M_4$ ,  $M_7$ ,  $M_8$ . In foreign region,  $\mathscr{A}$  who does not know  $U_i$ 's private keys  $p_u$ ,  $q_u$  and  $SID_j$ 's secret parameter  $A_{fs}$  is unable to decrypt  $M_{14}$  and  $M_{12}$ . Meanwhile, because of the one-way nature of hash function,  $\mathscr{A}$  cannot obtain  $U_i$ 's pseudo-identity  $HID_i$  from  $M_{11}, M_{13}, M_{16}, M_{17}$ . Due to the use of random numbers in each round of interaction, the untraceability of the user is guaranteed.

#### 4) RESISTANCE TO SMART CARD ATTACK

Through the side channel attack,  $\mathscr{A}$  can obtain the secret parameters stored in  $SC_i$  and use them. In our scheme, when the adversary obtains  $U_i$ 's  $\{A_i, B_i, C_i, \theta_i\}$  stored in  $SC_i$ , he/she can also not obtain the legitimate user's identity, password, and biometric information. The first step of user login is that  $U_i$  inputs his/her  $ID_i$ ,  $PW_i$ ,  $BIO_i$ , then the terminal computes  $\sigma_i$  using  $BIO_i$  and  $\theta_i$ .  $\mathscr{A}$  cannot calculate the true  $\sigma_i$  on account of having no correct  $BIO_i$ . Therefore, the request for a login will be rejected in this step. Furthermore, even if the adversary can get through this step, he/she cannot compute  $M_1, M_2$  without the correct  $HID_i$ .

#### 5) RESISTANCE TO REPLAY ATTACK

Timestamps are adopted in our scheme to resist the replay attack. Meanwhile, random numbers are taken during the interaction of the protocol to ensure the freshness and independence of the messages. As a result, the proposed scheme is resistant to replay attack.

#### 6) RESISTANCE TO PRIVILEGED INSIDER ATTACK

Assuming that the adversary is a malicious privileged node, he/she can obtain a user's login request information  $\{HID_i, HPW_i\}$ , but due to the one-way nature of the hash function and the biometric key data  $\sigma_i$ ,  $\mathscr{A}$  cannot obtain the password  $PW_i$  through  $HPW_i$ . Thus the proposed scheme can resist the privilege insider attack.

#### 7) ILLEGAL LOGIN DETECTION

When a user inputs an incorrect identity, password, or biometric information, the mobile device can quickly detect an illegal login and abort the session. In our scheme, when a user inputs incorrect information, the correct verification parameter  $B_i$  cannot be generated, and the mobile device will reject the user's login request. The mechanism described above can reduce communication and computation costs.

#### 8) FORWARD SECRECY

Rabin is leveraged to ensure forward secrecy in the proposed scheme. In both home and foreign regions,  $U_i$  and  $SN_j$  can establish a common symmetric session key  $SK = h_1(HID_i||SID_j||r_u||r_s)$  where  $r_u$  is a random number created by  $U_i$  and  $r_s$  is a random number generated by  $SN_j$  and updated at each session round. Even if the long-term secret values are compromised, the previous session key cannot be corrupted because the adversary has to resolve an intractable *IFP* in order to obtain  $\{r_u, r_s\}$ . The specific conditions are described in the following. If an adversary obtains  $\{A_i, B_i, C_i, \theta_i\}$  that are stored in user's  $SC_i$ , he/she still cannot get  $\{r_u, r_s\}$  resulting in failing to compromise

the previous session key. Similarly, there are identical results on gateway and sensor. Furthermore, even though  $\mathscr{A}$  gets three tuples of long-term secrets  $\{A_i, B_i, C_i, \theta_i\}$ ,  $\{HID_i, r_h\}$ ,  $\{SID_j, A_{gs}\}$  simultaneously, the consequence is the same as above. Therefore, this scheme achieves good forward secrecy.

# 9) RESISTANCE TO DESYNCHRONIZATION ATTACK

In our scheme, users and gateway nodes do not store any identical secret parameters, and all entities involved in the session do not need to update any information at the end of this session. Therefore, this scheme is resistant to desynchronization attack.

# 10) RESISTANCE TO IMPERSONATION ATTACK

Assuming that the adversary tries to participate in the session by impersonating as a legitimate user node, the legitimate information  $M_1, M_2, T_1$  needs to be generated. However, since the parameters  $HID_i, r_h^*, A_h$  cannot be obtained,  $\mathscr{A}$  fails to generate  $M_1, M_2$ .  $\mathscr{A}$  cannot forge a legitimate authentication request in polynomial time. Moreover,  $\mathscr{A}$  cannot forge legitimate information without the private key of the gateway node, so this scheme can resist the gateway node impersonation attack. Similarly,  $\mathscr{A}$  needs  $A_{gs}$  to generate valid messages  $M_5, M_6, M_7, M_8$  when simulating a legitimate sensor node, so this scheme can resist the sensor node impersonation attack.

# C. PROVABLE SECURITY

# 1) BASIC KNOWLEDGE OF PROVABLE SECURITY

Based on the security models of previous work in literature [31], [36], we verifies the security of the proposed scheme utilizing ROM.

There are three types of communication entities in the proposed scheme, i.e., user  $U_i$ , gateway GWN, and sensor  $S_j$ . Each entity has an independent number and can be considered an oracle. Supposing that the oracles  $\prod_{i=1}^{u} \prod_{i=1}^{v} \prod_{i=1}^{v} \prod_{i=1}^{t} for U_i, GWN$ , and  $S_j$  respectively, where u, v, t are instances of  $U_i$ , GWN,  $S_j$  respectively, all the above oracles can output three states {*accept*, *reject*,  $\perp$ }. When the last expected message is received,  $\prod^t$  becomes *accept*; otherwise,  $\prod^t$  becomes *reject*. When instances  $\prod_{i=1}^{t_1} \prod_{i=1}^{t_2} n^{t_2}$  satisfy the three conditions below, they are called partnerships.

1. Both  $\prod^{t_1}$  and  $\prod^{t_2}$  are *accept*.

2.  $\prod^{t_1}, \prod^{t_2}$  are mutual authentication and have identical session identifiers.

3.  $\prod^{t_1}, \prod^{t_2}$  cooperate with each other, and if the session key *SK* shared by the user node and the sensor node has not been asked for a *Reveal* query,  $\prod^{u}_{U_i}, \prod^{t}_{SN_k}$  can be considered as fresh.

In the ROM,  $\mathscr{A}$  can compromise the security of the authentication information and session key by using queries from oracles. The adversary model is defined as shown below, and this scheme assumes that  $\mathscr{A}$  has the following capabilities:

*Execute*( $\prod^{u}, \prod^{v}, \prod^{t}$ ): This query simulates a passive eavesdropping attack. If  $\prod_{U_{i}}^{u}, \prod_{GWN}^{v}, \prod_{SN_{k}}^{t}$  meets the

execution rules, the oracle executes the protocol and sends the transcript of all transmitted messages to  $\mathscr{A}$ .

Send( $\prod^{t}, m$ ): This query simulates an active attack between  $\mathscr{A}$  and instance  $\prod_{SN_{k}}^{t}$ , where  $\mathscr{A}$  sends messages to  $\prod_{SN_{k}}^{t}$  and  $\prod_{SN_{k}}^{t}$  returns the processing result of the message to  $\mathscr{A}$ .

*Reveal*( $\prod^{t}$ ): This query can help  $\mathscr{A}$  to obtain the session key *SK* generated by user  $\prod^{t}$ .

 $Corrupt(\prod_{U_i}^u, a)$ : This query can help  $\mathscr{A}$  obtain the information stored on the user's mobile device or password  $PW_i$ . The notice is that  $\mathscr{A}$  is unable to obtain two types of authentication information at the same time. Otherwise,  $\mathscr{A}$  will be indistinguishable from a legitimate user. There are listed as follows:

1. a = 0,  $\mathscr{A}$  acquires password via this query.

2. a = 1,  $\mathscr{A}$  acquires all values in the mobile device via this query.

*Test*( $\prod^{t}$ ): This query simulates an active attack and can measure the semantic security of the session key. Envision a challenger who flips a coin to define a bit *b*. If the oracle cannot meet *accept*, it returns an empty symbol  $\perp$ . Otherwise, if *b* = 1, then the response is the session key at that instance, but if *b* = 0, then the response is a completely random string of the same length as the session key. The adversary's final output is a bit *b*' which is its own guess at the value of *b*. Then we say that  $\mathscr{A}$  wins the security game if and only if b' = b.

# 2) PROCEDURE OF PROVABLE SECURITY

Definition 1: *P* is used to represent the security authentication scheme described in this section, *A* is used to represent  $\mathscr{A}$ who can break our scheme in polynomial time, and *D* is used to represent the uniformly distributed password dictionary.  $q_{hash}$ , |hash|,  $q_{send}$ , |D| and  $Adv_p^{IFP}$  are respectively used to represent the number of one-way hash queries, the space of one-way hash functions, the number of queries, the size of *D* and the advantage of  $\mathscr{A}$  corrupt *IFP*. Hash function is modeled as a random oracle. There are

$$Adv_p^{AKA}(\mathscr{A}) \le \frac{(q_{hash})^2}{|Hash|} + \frac{2q_{send}}{D} + 2Adv_p^{IFP}$$
 (1)

*Proof: Game 0~4* are defined to describe the entire process. For each *Game*, defining the event  $WG_0$  represents  $\mathscr{A}$  performing  $Test(\prod^t)$  query and successfully guessing the bit *b* to win the game.

**Game 0**: This game simulates a real attack on the protocol by the adversary  $\mathscr{A}$ . At the start, choosing bit *b*, according to the above definition, there is:

$$Adv_p^{AKA}(\mathscr{A}) = |2Pr|WG_0| - 1|$$
(2)

**Game 1**: In this game,  $\mathscr{A}$  is able to perform  $Execute(\prod^{u}, \prod^{v}, \prod^{t})$  query to simulate an eavesdropping attack. By performing *Test* query,  $\mathscr{A}$  can determine its return value as a session key or a random string. Analyzing the session key generates, where the user generates  $HID_i$ ,  $r_u$ ,  $M_1$ , the sensor node generates  $SID_j$ ,  $r_s$ ,  $M_5$ .  $\mathscr{A}$  cannot compute

the session key without the above secret values. Accordingly,

$$Pr|WG_1| = Pr|WG_0| \tag{3}$$

*Game 2*: *Game 2* adds the oracles *Send* and *Hash* to the foundation of *Game 1*. In this game, the active attack is mainly simulated, where the attack tries to forge legitimate information by repeatedly querying the random oracle *Hash* to generate collisions. However, since all the messages transmitted in the channel contain random numbers and entity identifiers, the oracle *Send* will not generate collisions. According to the birthday paradox, it is obtained that:

$$Pr|WG_2| - Pr|WG_1| \le \frac{q_{hash}^2}{2|Hash|} \tag{4}$$

**Game 3**: Game 3 adds the oracle CorruptMobileDevice  $(\prod_{U_i}^u, a)$  to the foundation of Game 2. This game mainly simulates a user's mobile device theft attack combined with a dictionary attack, where  $\mathscr{A}$  tries to obtain the user's password. Suppose that the times that  $\mathscr{A}$  enters the wrong password are limited by the system, thus it is obtained that:

$$Pr|WG_3| - Pr|WG_2| \le \frac{q_{send}}{|D|} \tag{5}$$

**Game 4**: Game 4 is the final game. In order to get the session key SK,  $\mathscr{A}$  needs to get  $HID_i$ ,  $SID_j$  and random numbers  $r_u$ ,  $r_s$ . Assume that  $\mathscr{A}$  can obtain the secret information stored in mobile device, and is able to obtain the information in the channel through eavesdropping attacks. However, due to the irreversibility and collision resistance of the one-way hash function,  $\mathscr{A}$  cannot extract useful information from  $M_2$ ,  $M_3$ ,  $M_4$ ,  $M_7$ ,  $M_8$ ,  $M_9$ . Similarly, in order to extract  $HID_i$ ,  $SID_j$ ,  $r_u$ ,  $r_s$  from the messages  $M_1$ ,  $M_5$ ,  $\mathscr{A}$  needs to have the ability to solve the *IFP*. As a result,

$$Pr|WG_4| - Pr|WG_3| \le Adv_P^{IFP} \tag{6}$$

In addition,  $\mathscr{A}$  executes all the oracles, but it does not have the advantage of correctly guessing the bit *b*, therefore, we have

$$Pr|WG_4| = \frac{1}{2} \tag{7}$$

According to equations (2) and (3), we can get:

$$\frac{1}{2}Adv_p^{AKA}(\mathcal{A}) = |Pr|WG_0| - \frac{1}{2}| = |Pr|WG_1| - \frac{1}{2}|$$
(8)

In conjunction with equations (3), (4), (5), and (6), there will be:

$$|Pr|WG_{1}| - |Pr|WG_{4}| \leq |Pr|WG_{1}| - Pr|WG_{2}| + Pr|WG_{2}| - Pr|WG_{4}|| \leq |Pr|WG_{1}| - Pr|WG_{2}| + Pr|WG_{2}| - Pr|WG_{3}| + Pr|WG_{3}| - Pr|WG_{4}|| \leq |Pr|WG_{1}| - Pr|WG_{2}|| + |Pr|WG_{2}|| - Pr|WG_{3}|| + |Pr|WG_{3}| - Pr|WG_{4}|| \leq \frac{q_{hash}^{2}}{2|Hash|} + \frac{q_{send}}{|D|} + Adv_{P}^{IFP}$$
(9)

As a result, we can obtain the following consequence:

$$Adv_p^{AKA}(\mathscr{A}) \le \frac{(q_{hash})^2}{|Hash|} + \frac{2q_{send}}{D} + 2Adv_p^{IFP}$$
(10)

Hence the safety and validity of our scheme are proved.

# **V. THE PERFORMANCE COMPARISON**

This section describes the performance comparison between the proposed and other corresponding schemes. We compare the security attribute that each scheme can achieve, the computational cost, and the communication cost, respectively, where Case 1 signifies the scheme applied in the home region and Case 2 denotes the protocol created in the foreign region.

# A. SECURITY ATTRIBUTE COMPARISON

Table 2 describes the security features our scheme and other pertinent schemes can achieve, where " $\checkmark$ " means that the security property is satisfied, "×" means that it is not, and "-" means that the security property is not mentioned in their schemes. From Table 2, none of these literature [17], [22], [23], [24], [26], [28] can achieve forward secrecy. Literature [29] can achieve forward secrecy because their scheme takes advantage of ECC operations, which produce more overhead than our scheme. It can be seen that only our scheme can achieve all the security attributes listed in Table 2. Therefore, it can be concluded that the proposed protocol has better security attributes compared with other schemes.

# B. COMPARISON OF COMPUTATIONAL COST

The computational costs of authentication protocols are evaluated according to all the required calculations. To demonstrate the superiority of our scheme, the computational costs of several protocols are shown in Table 3, according to the results of experiments in [17] and [37]. "fe" denotes the fuzzy extractor, and one fe computation roughly costs 0.0171 s (s denotes second). "ed" denotes the symmetric encryption or decryption operation (using AES-128), and one ed computation roughly costs 0.0056 s. "h" denotes a hash function, and one h computation roughly costs 0.00032 s. "b" represents the run time of a BioHash operation. "m" denotes the modular squaring operation (the encryption operation in Rabin), and one m computation roughly costs 0.00088 s (when we set the length of modular |N| = 512). "qr" denotes a module-square root operation (the decryption operation in Rabin), and one qr computation roughly costs 0.0192 s. "ecm" signifies ECC point multiplication, and one ecm computation roughly costs 0.0171 s. "eca" signifies ECC point addition, and one eca computation roughly costs 0.0044 s.

Since only the computational resources of sensor nodes are usually limited in WSNs, this scheme primarily focuses on computational costs on the sensor node side. Table 3 compares the computational costs for *HGWN* and *FGWN*. Compared with [22], [23], [24], and [26], the computational costs on the sensor side increased slightly, but the performance improved. However, compared with [17] and [28] that cannot support multi-gateway access, our protocol has a much

	Case-2	8	4416
Ours	Case-1	5	5504
	Case-2	9	9600

smaller overhead on the sensor side in *HGWN*. Furthermore, the computational cost on the sensor side is significantly less than that in literatures [29], [30]. In summary, the proposed protocol achieves better security attributes with lower computational costs.

#### C. COMPARISON OF COMMUNICATION COST

According to literature [17], [38], the following assumptions are used to calculate the communication cost. The bit sizes required for random nonce, timestamp, hash output and ECC

point are, respectively, 160 bits, 32 bits, 160 bits, and 320 bits. Additionally, modular exponentiation and inversion operations are performed using 1024-bit modulus to guarantee security. In the proposed scheme, the transmitted messages in the home region during the login and authentication phase  $\{M_1, M_2, T_1\}$ ,  $\{M_3, M_4, T_2\}$ ,  $\{M_5, M_6, M_7, M_8, T_3\}$ ,  $\{M_5, M_8, M_9, T_4\}$ , and  $M_6^*$  require (1024 + 160 + 32) = 1216 bits, (160+160+32) = 352 bits, (1024+1024+160+160+32) = 1376 bits, and 160 bits, respectively.

Furthermore, the transmitted messages in the foreign region during the login and authentication phase  $\{M_1, M_2, T_1\}, \{M_4, M_5\}, \{M_6, M_7\}, \{M_8, M_9, T_4, R_1\},\$  $\{M_{10}, M_{11}, T_5\}, \{M_{12}, M_{13}, T_6\}, \{M_{14}, M_{15}, M_{16}, M_{17}, T_7\},\$  $\{M_{14}, M_{17}, M_{18}, T_8\}$ , and  $M_{15}^*$  require (1024 + 160 + 32) =1216 bits, (1024 + 160) = 1184 bits, (1024 + 160) =1184 bits, (160 + 160 + 32 + 160) = 512 bits, (1024 + 160) = 512 bits, 160 + 32 = 1216 bits, (160 + 160 + 32) = 352 bits, (1024 + 1034 + 160 + 160 + 32) = 2400 bits, (1024 + 1034) = 1000 bits, (1024 + 1000) = 1000 bits, (1000) = 1000 bits, (1000)160 + 160 + 32 = 1376 bits and 160 bits, respectively. An identical method is used to calculate the relative schemes' communication cost, and their results are listed in Table 4. The communication of our protocol is slight higher because we transmitted the encryption message over the open channel. We take advantage of Rabin's ability to encrypt messages to ensure the scheme's security, which produces slightly higher communication costs while achieving more security attributes.

#### **VI. CONCLUSION**

We propose a lightweight user authentication and key agreement scheme for multi-gateway based wireless sensor networks using the Rabin cryptosystem. In the proposed protocol, we used lightweight cryptographic primitives such as the hash function, the encryption of Rabin, and the XOR operation to reduce the overhead. This protocol is proven to have good authentication and confidentiality through formal analysis, informal analysis, and provable security. Furthermore, because of the introduction of the public key cryptosystem, this scheme achieves forward secrecy. Finally, compared with the corresponding schemes, the proposed scheme provides more security features while requiring less computational overhead.
