

ElectroNet—A Deep-Learning-Based Sound Coding Strategy for Cochlear Implants

Enoch Hsin-Ho Huang^{1b}, Rong Chao^{1b}, Yu Tsao^{1b}, *Senior Member, IEEE*, and Chao-Min Wu^{2b}, *Member, IEEE*

Abstract—ElectroNet, a deep-learning-based sound coding strategy for the cochlear implant (CI), is proposed to emulate the advanced combination encoder (ACE) strategy by replacing the conventional envelope detection using various artificial neural networks. The extended ElectroNet-CS strategy further incorporates the channel selection (CS). Network models of deep neural network (DNN), convolutional neural network (CNN), and long short-term memory (LSTM) were trained using the fast Fourier transformed bins and channel envelopes obtained from the processing of clean speech by the ACE strategy. Objective speech understanding using short-time objective intelligibility (STOI) and normalized covariance metric (NCM) was estimated for ElectroNet using CI simulations. Sentence recognition tests for vocoded Mandarin speech were conducted with normal-hearing listeners. DNN, CNN, and LSTM-based ElectroNets exhibited strong correlations to ACE in objective and subjective scores using mean squared error (MSE), linear correlation coefficient (LCC), and Spearman’s rank correlation coefficient (SRCC). The ElectroNet-CS strategy was capable of producing N-of-M compatible electrode patterns using a modified DNN network to embed maxima selection, and to perform in similar or even slightly higher average in STOI and sentence recognition compared to ACE. The methods and findings demonstrated the feasibility and potential of using deep learning in the CI coding strategy.

Index Terms—Channel selection (CS), cochlear implant (CI), deep learning, sound coding strategy, vocoder simulation.

I. INTRODUCTION

THE COCHLEAR implant (CI) is a revolutionary device that enables people with severe-to-profound hearing loss to restore a partial sense of hearing [1], [2], [3], [4] and, hence, to improve their cognitive functions [5], [6]. With the design of an external CI sound processor and an internal device to stimulate the auditory nerves in meaningful pulse patterns, the lives of hundreds of thousands of CI users have been changed. Contributions from multidisciplinary researchers have enabled the CI today to help not only lip-reading but also speech recognition in quiet conditions [1], [2], [3], [4]. Apart from the present achievements, challenges of electric hearing are still present in understanding speech under interferences, tonal languages, and music [1], [2], [3], [4]. Furthermore, the difficulties in listening to speech through face masks, at increased physical distance, and on the Internet have been getting noticed during the recent COVID-19 pandemic [7], [8]. Therefore, the continual improvement for the sound processing of the CI is still in great demand.

Deep learning [9], [10], a subset of artificial intelligence (AI) and machine learning, has an increasing influence and potential on the innovation of the CI. In the recent decade, AI-based approaches have changed hearing healthcare [11] and various aspects of the “AI + CI” research [12], including prognosis estimation [13], electrode placement [14], robotic surgery [15], mapping [16], and sound signal processing [17], [18]. In addition, the success of deep learning in general audio processing [19], [20] and hearing aids [21], [22] may also change CI sound processing.

In recent years, some CI sound processing approaches have started to shift from traditional to deep-learning-based solutions. Distinctive types of network architectures, including deep (feedforward) neural network (DNN) [23], [24], [25], [26], convolutional neural network (CNN) [27], [28], [29], and recurrent neural network (RNN) [30], [31], [32], have been investigated for the CI. Among the aforementioned studies, deep-learning-based speech enhancement approaches outperform traditional ones in both simulations and CI recipients [23], [24], [25], [26], [27]. Furthermore, multimodal [28], [29] and music mixing [33], [34], [35] approaches have been demonstrated in performing complex signal processing tasks to improve CI recipients’ speech intelligibility and enjoyment of music, respectively. However, these deep-learning-based approaches typically modify the front-end processing only. For the remaining signal processing, particularly for the core sound coding strategy, the efficacy of utilizing deep learning approaches has to be thoroughly investigated.

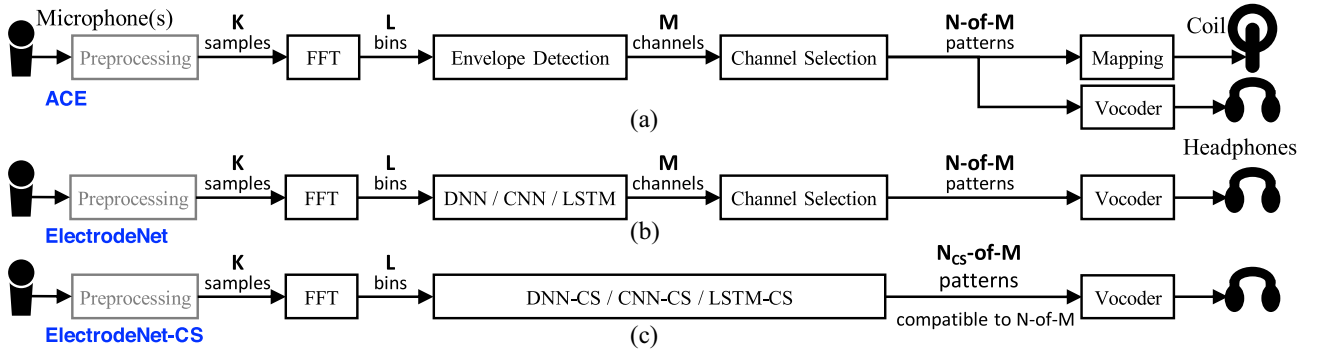

Fig. 1. Signal processing for the (a) ACE, (b) ElectrodeNet, and (c) ElectrodeNet-CS coding strategies. The ElectrodeNet strategy uses a neural network, such as a DNN, CNN, or LSTM, to mimic the envelope detection of the ACE strategy. The data formats between the processing stages are denoted as K samples, L bins, M channels, and the N -of- M electrode stimulation patterns. The ElectrodeNet-CS strategy uses a single network containing a custom topk layer to replace both the envelope detection and CS stages of ACE and produces the N_{CS} -of- M patterns compatible to the N -of- M patterns ($N_{CS} \leq N$). The networks for ElectrodeNet-CS are referred to as DNN-CS, CNN-CS, and LSTM-CS. The preprocessing stages in gray are bypassed in this study.

The CI sound coding strategy plays a key role in representing acoustic signals as recognizable stimulation patterns [36]. Continuous interleaved sampling (CIS) [37] and advanced combination encoder (ACE) [38] are two popular coding strategies with reasonably good performance for speech understanding in quiet, but they have already existed for 20–30 years. More recent commercial coding strategies, including MP3000 [39], fine structure processing (FSP) [40], HiRes 120 and Optima [41], [42], and CRYSTALIS [43], have been proposed with some advancements. However, most coding strategies, typically based on traditional signal processing, still need improvements [36], [44].

This study aims to identify whether a neural network can perform the signal processing procedures of traditional coding strategies. In the AI era, the unknown performance and benefits of using deep-learning-based coding strategies at the expense of computation are of interest for understanding. Furthermore, the core signal processing techniques of traditional coding strategies, envelope detection (extraction) and channel selection (CS), are not differentiable, and, hence, unable to be directly combined and optimized with other neural-network-based front-end and post-processing modules in a joint-training and end-to-end learning manner [45], [46], [47]. Consequently, ElectrodeNet was proposed to demonstrate the concepts of deep-learning-based CI coding strategy using DNN, CNN, and long short-term memory (LSTM) network models to imitate the envelope detection of the ACE strategy [48]. A comprehensive study was carried out for the performance correlation between ElectrodeNet and ACE using objective evaluation with vocoded sentences for the factors of network architecture, data set language, and noise type. Subjective listening tests were conducted with normal-hearing Mandarin speakers.

Since the neural network-based envelope detection process in ElectrodeNet might not fit well to the conventional CS process, ElectrodeNet-CS, an extended variant for ElectrodeNet containing a CS layer in a modified DNN network, was further proposed. The ElectrodeNet-CS strategy was trained to optimize the overall CS decision results in attempt to represent speech features in the selected channels. With the advantage of formulating envelope detection and CS in a single network, even slight improvements in speech intelligibility

for ElectrodeNet-CS in comparison to ACE and ElectrodeNet would be inspiring. The current work motivates future research attempting to integrate various front-end and post-processing with ElectrodeNet for different tasks and be optimized in a joint-training and end-to-end learning manner. We also anticipate that future CI devices will consist of multiple neural network modules, each handling a specific task, such as envelope detection, speech denoising, and acoustic scene classification. While current network models appear to require relatively large computational costs, advances in integrated circuits should overcome these limitations [49]. Therefore, this research can be considered as a pioneering work investigating the feasibility of ElectrodeNet other than its integration with front-end processing units, such as speech denoising and music separation, and as a preparation for the next-generation signal processing of the AI-powered CI system.

The remainder of this article is organized as follows. Section II describes the proposed ElectrodeNet and experimental methods. Section III presents the objective and subjective evaluation results. Section IV provides the discussions. Section V draws the conclusions.

II. METHODS

A. Strategy Architecture

This section reviews the fundamentals of the ACE strategy and artificial neural networks, and describes the design of the ElectrodeNet and ElectrodeNet-CS coding strategies.

1) *ACE*: ACE [38], the most common coding strategy used for Nucleus CI systems, is depicted in Fig. 1(a). Sounds collected by microphones are enhanced in the preprocessing stage. For the fast Fourier transform (FFT) filterbank, each short-time frame of generally $K = 128$ samples is Hann windowed and converted into $L = (K/2 + 1) = 65$ bins, where the magnitudes of the complex bins represent the spectral envelopes below 8 kHz. The envelope detection stage uses the power-sum combination method to merge L bins into M channels [50], where $M = 22$ intracochlear electrodes for the Nucleus-24 implant with two extra-cochlear ground electrodes. The CS stage, also known as N -of- M or maxima selection, picks N maxima with the largest amplitudes from M channels. The mapping stage adjusts stimulation levels based on the loudness

growth function (LGF) and personalized electric current units. Pulse patterns are transmitted from a coil via radio frequencies to the internal implant and may be synthesized as audible sounds for normal-hearing listeners using vocoders [51], [52]. The ACE strategy defined in Cochlear’s nucleus MATLAB toolbox (NMT) v4.31 [53] was used in this study.

2) *Artificial Neural Network*: Artificial neural networks, originally simulate the human neural system, have been developed into many distinct architectures over decades. A network consists of a number of neuron layers, and each neuron combines multiple inputs as a nonlinear output through an activation function. In the supervised learning procedure, the network is shaped by adjusting its interconnection weights based on labeled data using backpropagation. The test data is then passed through the learned network to obtain the predicted results in a process called model inference.

DNN, CNN, and LSTM are three commonly used deep learning networks. A DNN [54] or the multilayer perceptron (MLP) [55], is a feedforward network containing multiple hidden layers or dense layers, where neurons between adjacent layers are fully interconnected. A CNN typically consists of convolutional layers, pooling layers, and dense layers, and the convolution process is defined by the kernel size, padding, and stride [56]. The LSTM network [57] is a refined type of RNN [58] and designed to use cells and gates to operate as memory in processing sequences with different lengths over time.

3) *ElectrodeNet*: ElectrodeNet utilizes the artificial neural network in Fig. 1(b) to imitate the CI electrode output behaviors of the ACE strategy in Fig. 1(a). The same FFT filterbank and CS stages were preserved. Using supervised learning, a DNN, CNN or LSTM model learned to mimic the envelope detection of ACE. The network input layer was set to $L = 65$ neurons, which corresponded to the L real-valued bins of FFT magnitudes in ACE. Paired spectral–temporal matrices in L bins and M channels for clean speech processed by ACE were used to train each neural network. Electrode stimulation patterns were synthesized as audible sounds using the tone vocoder of NMT and normalized in sound levels. The deep learning networks were implemented with PyTorch 1.1.0, and the rest of the processing was developed in MATLAB R2020a. To focus on the performance of coding strategies, the preprocessing stages in Fig. 1 were bypassed in this study.

The neural networks for ElectrodeNet were configured using hyperparameters, including the number of neurons and layers, and some learning settings. Table I shows the architectures of the DNN, CNN, and LSTM networks investigated. The DNN model had four dense layers containing 1024, 512, 256, and 22 neurons, respectively. The CNN model had two layers of 1-D convolution, including 1024 channels and 512 channels with a kernel size of 3 and padding of 2. The convolutional layers were followed by two dense layers consisting of 256 neurons and 22 neurons, and no pooling layers. The LSTM network used one 1-D convolution with 1024 channels, one unidirectional LSTM layer with 512 nodes, and two fully connected layers with 256 and 22 neurons, respectively. For the numbers of parameters shown in Table I, the DNN is the smallest model and the LSTM is the largest model. The common activation function was the rectified linear unit (ReLU) [59]. All the

TABLE I
NETWORK ARCHITECTURE AND NUMBER OF PARAMETERS

Network	DNN	CNN	LSTM	DNN-CS	Size
Layer	input	input	input	input	65
	dense 1	conv. 1	conv. 1	dense 1	1024
	dense 2	conv. 2	lstm 1	dense 2	512
	dense 3	dense 1	dense 1	dense 3	256
	dense 4	dense 2	dense 2	dense 4	22
	-	-	-	custom CS	22
# Params	0.73M	1.91M	3.49M	0.73M	-

Note: The DNN, CNN, and LSTM networks share the same size for different types of network layers. The DNN-CS network includes a custom CS layer based on PyTorch’s topk function.

TABLE II
PERCENTAGE FOR NUMBER OF CHANNELS SELECTED BY ELECTRODENET-CS AMONG TMHINT SPEECH FRAMES

Network Type	Network Maxima (N_{topk})	# Channels Selected (N_{CS}) (%)		
		$< N_{\text{topk}}$	$= N_{\text{topk}}$	$> N_{\text{topk}}$
DNN-CS	8, 9, 10, 11	0	100	0
	12	1.98	98.02	0
	13	1.91	98.09	0
	14	0.01	99.99	0

three models were trained using the L_1 norm (mean absolute error, MAE) as the loss function against the ACE envelope detection phase. The Adam optimizer [60] was used with a learning rate of 0.0001, and the number of iterations was 100 epochs. Causal implementations were used to fit the scenario of real-time signal processing.

4) *ElectrodeNet-CS*: The ElectrodeNet-CS strategy, a refined variant of ElectrodeNet including the CS stage, is depicted in Fig. 1(c). The DNN, CNN, or LSTM network used in ElectrodeNet in Fig. 1(b) is modified as a DNN-CS, CNN-CS, or LSTM-CS network, which includes an extra CS layer implemented using Pytorch’s topk function [61] to select the N_{topk} largest channels with positive values. In contrast to the independent CS process in ElectrodeNet, the CS layer, here, takes part in the training and optimization process of the neural network weights and the ReLU function was used subsequently to the network model. Table I shows that the DNN-CS model contains the four dense layers of 1024, 512, 256, and 22 neurons as the DNN model and an extra custom topk layer of 22 neurons. The number of parameters is equivalent between the DNN model and the DNN-CS model. The training data set used for the DNN-based ElectrodeNet, paired spectral–temporal matrices in L bins and M channels for clean speech processed by the ACE strategy in Fig. 1(a), was also used to trained the DNN-CS model. The training configuration was designed to preserve the most important information in the N_{topk} channels selected by the network and to allocate data with smaller envelopes to the remaining $M - N_{\text{topk}}$ channels using the L_1 norm computed across the entire M channels.

The ElectrodeNet-CS strategy essentially conformed to the prerequisite N-of-M stimulation patterns of the ACE strategy. The number of channels selected by the DNN-CS network for each speech frame, N_{CS} , was variable and mostly equal to the N_{topk} setting of the CS layer. Table II shows the percentage of N_{CS} channels selected among all the Mandarin speech frames used for testing in this study. For $N_{\text{topk}} = 8, 9, 10,$

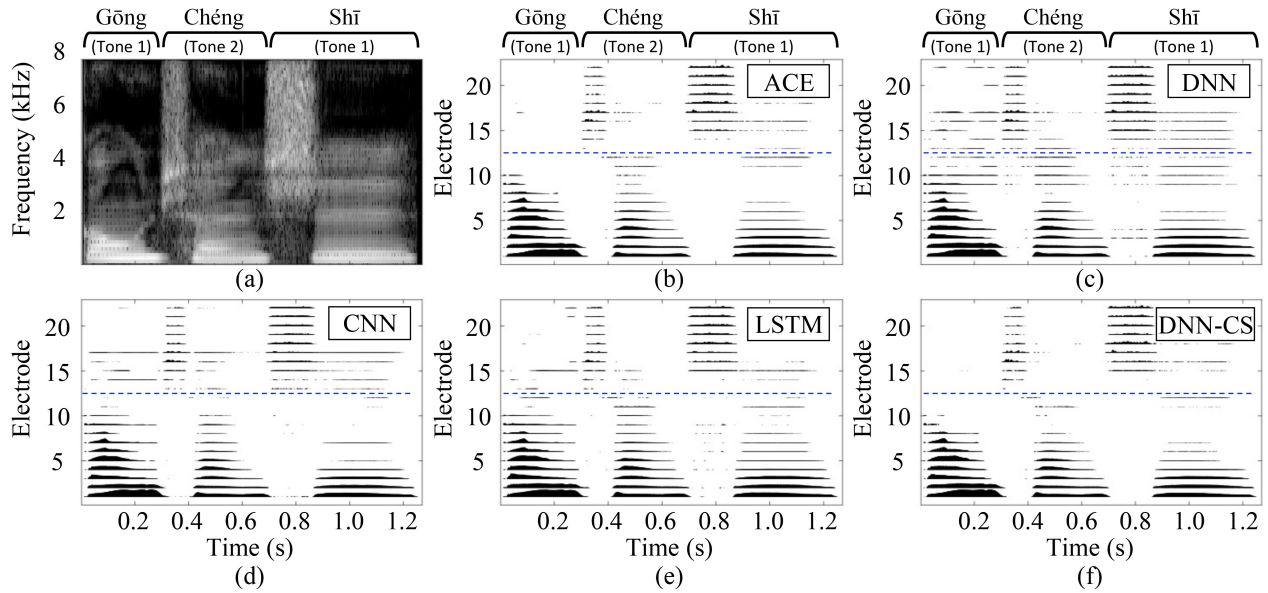

Fig. 2. (a) Spectrogram of trisyllabic Mandarin phrase “Gōng Chéng Shī” (“Engineer” in Chinese with tones 1, 2, and 1) uttered by a female speaker. The electrodograms are processed by (b) ACE strategy and ElectrodeNets based on (c) DNN, (d) CNN, (e) LSTM, and (f) DNN-CS models. The blue-dotted lines indicate similar stimuli for the ACE strategy and the DNN-CS-based model below Channel 12 (1937 Hz).

and 11, the N_{CS} selected were always equivalent to N_{topk} . For the other DNN-CS networks, the 98.02%, 98.09%, and 99.99% of speech frames were equivalent to the design as $N_{CS} = N_{topk} = 12, 13,$ and $14,$ respectively. Less than 2% of the speech frames for the three cases were with fewer channels than design ($N_{CS} < N_{topk}$). Since the number of channels selected were always no greater than the target maxima setting ($N_{CS} \leq N_{topk}$), the corresponding N maxima in the ACE strategy, the N_{CS} -of- M stimuli generated by the ElectrodeNet-CS strategy were compatible with the conventional N -of- M stimulation patterns.

B. Data Sets

Mandarin and English data sets were both used to investigate a tonal language and a nontonal language. The sampling frequency for both data sets was 16 kHz.

1) *Mandarin Data Set*: The Taiwan mandarin hearing in noise test (TMHINT) sentences [62] were used for both objective and subjective evaluations. The TMHINT material contains 16 phonemically balanced lists, each list has 20 sentences, and each sentence has ten syllables. Each syllable corresponds to a Chinese character with one of four primary lexical tones, tone 1 (high and flat), tone 2 (rising), tone 3 (falling then rising), and tone 4 (falling), or a neutral tone. Sound files recorded by Academia Sinica (AS) and the National Central University (NCU) were used for ElectrodeNet training and testing, respectively. In training, 320 clean sentences from Lists 9–16 of the TMHINT(AS) material spoken by a male and a female were used. Specifically, every two lists uttered by one of four male or female speakers were used for training and 160 sentences were for each gender (4 speakers \times 2 lists/speaker \times 20 sentences/list). In objective evaluation, Lists 1-8 of the TMHINT(NCU) material spoken by one male and one female (16 lists) were mixed with four types of noises, including speech shaped noise (SSN), white noise, street noise

and cafeteria babble, at seven signal-to-noise ratio (SNR) levels ($-10, -5, 0, 5, 10, 15$ dB, and quiet). For the listening tests, female sentences at four SNR levels ($-5, 0, 5$ dB, and quiet) with SSN were used. Sound levels were normalized between the TMHINT(AS) and TMHINT(NCU) sentences.

2) *English Data Set*: An English corpus was used in objective evaluation. Developed by research teams at Texas Instruments (TIs) and the Massachusetts Institute of Technology (MIT), TIMIT is a famous speech data set used for automatic speech recognition (ASR) [63]. The complete TIMIT data set consists of 6300 sentences spoken by 630 different speakers from eight major dialect regions in the United States. This study utilized 300 and 80 nonrepetitive sentences (150 and 40 speakers/gender) for training and testing, respectively.

C. Electrode Stimulation Patterns

Speech signals processed by the ACE and ElectrodeNet strategies with 12 maxima are illustrated in Fig. 2. The trisyllabic Mandarin phrase “Gōng Chéng Shī” (“Engineer” in Chinese with tones 1, 2, and 1) [64] has syllabic transitions at approximately 0.3 and 0.7 s. The spectrogram in Fig. 2(a) shows that the consonants of the second and third syllables mainly occur above 2 kHz and the three vowels with strong envelopes exist below 1 kHz. Similar trends can be observed in the electrodograms for the ACE strategy in Fig. 2(b) and ElectrodeNets based on DNN, CNN, LSTM, and DNN-CS networks in Fig. 2(c)–(f), respectively. In the first syllable “Gōng,” the “g” consonant (unaspirated velar voiceless stop /k/) is quite short to be clearly identified in all subfigures. The second and third consonants, “ch” (aspirated retroflex voiceless affricate /tʂʰ/) and “sh” (retroflex voiceless fricative /ʃ/), are in lengths of approximately 100 ms (0.3–0.4 s in the time axis) and 200 ms (0.7–0.9 s in the time axis), respectively. At the lower frequencies from Channel 1 (250 Hz) to Channel 8 (1125 Hz), the pulses with higher amplitudes represent vowels carrying

strong energy in comparison to relatively weak consonants. Some differences between ACE and ElectrodeNets, particularly the DNN case in Fig. 2(c), can be observed between Channel 9 (1250 Hz) and Channel 17 (3812 Hz) for the three vowels, but these pulses in the mid-to-high spectrum should only have small effect on vowels dominated by low frequencies.

The electrodiagram for the ElectrodeNet-CS strategy based on the DNN-CS model is generally similar to that for ACE. In Fig. 2, the electrode stimulation patterns under the blue dotted lines are similar between the ACE strategy and the ElectrodeNet-CS strategy compared to the other three ElectrodeNets without the CS network layer. Specifically, the stimuli for ACE and ElectrodeNet-CS exhibit comparable patterns below Channel 12 (1937 Hz), the low-to-mid frequency range important for speech recognition.

D. Objective Evaluation

This section explains the objective predictors, experimental factors, and correlation computations for objective evaluation.

1) *Predictors*: Two objective predictors, short-time objective intelligibility (STOI) [65] and normalized covariance metric (NCM) [66], [67] were used to evaluate ElectrodeNet's performance in speech intelligibility. Objective predictors have been widely used in estimating speech intelligibility, quality, and output SNR for assistive hearing devices [68], [69], [70], [71]. Among these predictors, STOI and NCM are two intrusive predictors for speech intelligibility using a reference speech and a processed version of the speech. STOI has a high correlation with speech intelligibility and has been used in CI studies on speech enhancement and coding strategies [25], [28], [29], [44], [70], [72], [73], [74], [75], [76]. NCM is another frequently used indicator for evaluating speech comprehension in CI sound processing [25], [29], [70], [72], [76], including for vocoded Mandarin speech [68]. In this study, STOI or NCM scores were computed between the clean original speech and the corresponding processed and vocoded speech.

2) *Experimental Factors*: The ElectrodeNet strategy was objectively evaluated for experimental factors of network architecture, data set language, and noise type.

- 1) *Network Architecture*: The DNN, CNN, and LSTM-based ElectrodeNets were investigated to clarify the efficacy of the deep, convolutional, and recurrent network architectures.
- 2) *Data Set Language*: The DNN-based ElectrodeNet was trained and tested using the TMHINT data set or the TIMIT data set to evaluate the objective performance with different languages.
- 3) *Noise Type*: The DNN-based ElectrodeNet was evaluated for speech understanding with four types of noises (SSN, white noise, street noise [77], and cafeteria babble [77]) at seven SNR levels (−10, −5, 0, 5, 10, 15 dB and quiet).

The three factors were examined for their effects on the correlations of objective speech intelligibility between ElectrodeNet and ACE.

3) *Correlations in Objective Speech Intelligibility*: The relationships between ElectrodeNet and the ACE strategy in speech intelligibility were evaluated using mean squared

error (MSE), linear correlation coefficient (LCC) [78], and Spearman's rank correlation coefficient (SRCC) [79]. The MSE measured the average of the squares of the differences in speech intelligibility scores between ACE and ElectrodeNet. The closer to 0 the MSE scores, the smaller the errors between the two strategies.

The LCC between ACE and ElectrodeNet is computed as

$$\text{LCC} = \rho = \frac{\text{cov}(SI_{\text{ACE}}, SI_{\text{ElectrodeNet}})}{\sigma_{SI_{\text{ACE}}} \sigma_{SI_{\text{ElectrodeNet}}}} \quad (1)$$

where SI is the speech intelligibility for a coding strategy, $\text{cov}(X, Y)$ is the covariance of X and Y , and σ is the standard deviation. Therefore, the LCC is the covariance of speech intelligibility for ACE and ElectrodeNet divided by the product of standard deviations of speech intelligibility for the two strategies. The SRCC is computed as

$$\text{SRCC} = \rho_s = \frac{\text{cov}(\text{Rank}(\text{ACE}), \text{Rank}(\text{ElectrodeNet}))}{\sigma_{\text{Rank}(\text{ACE})} \sigma_{\text{Rank}(\text{ElectrodeNet})}} \quad (2)$$

where $\text{Rank}(\cdot)$ is the resulting rank in speech intelligibility for one coding strategy. The ranks for n sentences are generally distinct integers $1, 2, \dots, n$ with respect to the ascending order of speech intelligibility, and average ranks are used for repeated intelligibility scores. In both (1) and (2), the order of the two coding strategies does not change the values of LCC and SRCC. Typically, a correlation coefficient greater than 0.7 or 0.8 indicates a strong correlation [80], [81]. The closer the LCC and SRCC scores to 1, the higher the correlations in speech intelligibility between the two strategies. Consequently, the desired results for correlations between ElectrodeNet and ACE are small MSEs close to 0 and large LCCs and SRCCs close to 1.

4) *ElectrodeNet-CS*: The ElectrodeNet-CS strategy based on the DNN-CS model was evaluated using objective predictors for maxima settings $N = 8$ and $N = 12$. The STOI and NCM scores were measured for ACE, the DNN, CNN, and LSTM-based ElectrodeNets, and the DNN-CS model-based ElectrodeNet-CS strategy. Statistical analyses were conducted for average list scores using IBM SPSS Statistics 21 (released 2012) with a significance level of $\alpha = 0.05$.

E. Subjective Evaluation

Two listening experiments were conducted using CI simulations. The first experiment focused on the speech intelligibility of the DNN and CNN-based ElectrodeNets, and the second one evaluated the ElectrodeNet-CS strategy. The procedures were approved by an institutional review board (IRB).

1) *Listening Experiment 1*: Listening tests were performed with two groups of normal-hearing listeners to investigate the correlations between ACE and two ElectrodeNet strategies. Forty native Mandarin speakers (age 20–29) were randomly divided into two test groups to evaluate the performance of the DNN or CNN-based ElectrodeNet compared to the ACE strategy. In the DNN group, 14 male and 6 female subjects were with an average age of 22.3 years, while 15 male and 5 female subjects with an average age of 22.6 were assigned to the CNN group. All subjects had hearing thresholds no more than 25-dB HL at octave frequencies between 0.125 and 8 kHz

in pure tone audiometry (PTA). The sentence recognition test for each subject took about 45–60 min.

Speech intelligibility was measured for the ACE strategy and an ElectrodeNet strategy based on the DNN/CNN group assignment. Each subject listened to the simulated CI sound simultaneously played to both ears via Telephonics TDH-39P headphones in a sound isolation room. The experiment was carried out with NCU-CI, a MATLAB-based CI experiment platform with a graphical user interface in traditional Chinese [44], [48], [82]. In the practice session, each subject was instructed on the experimental procedure by being familiarized with sentences from List 16 of the TMHINT material presented at a fixed and comfortable sound level. Vocoded sentences processed by ACE and ElectrodeNet with maxima $N = 12$ were presented at four SNR levels in the order of -5 , 0 , 5 dB and quiet. At each SNR level, the order of ACE and ElectrodeNet was chosen randomly. For the eight test conditions (2 strategies \times 4 SNR levels), one of TMHINT Lists 1–8 was selected at random without replacement, and the 20 sentences for each condition were also presented in a random order. Each sentence was played only once and the subjects were encouraged to type the Chinese characters to the best of their ability. The speech intelligibility for each list was calculated as the average percentage of correct results for 200 syllables (10 syllables/sentence \times 20 sentences/list). Scores were given for each correct syllable, including a homophone, a different Chinese character with the correct pronunciation.

2) *Listening Experiment 2*: Sentence recognition tests were conducted with twenty normal-hearing listeners to investigate the DNN-based ElectrodeNet-CS strategy with two maxima configurations. Ten male and ten female native Mandarin speakers (age range 20–25 years, mean age of 21.7 years) participated the experiment. Four coding strategy conditions (ACE with $N = 8$ and 12 , and ElectrodeNet-CS with $N = 8$ and 12) were tested randomly for each SNR level. TMHINT Lists 1–8 were randomly tested for both ElectrodeNet-CS strategies. Owing to the limited sentences for listening tests, Lists 9–16, already used for training the two ElectrodeNet-CS strategies, were tested for the two ACE conditions. The rest procedure was similar to that used in Experiment 1. Each subject spent about 60–90 min in this experiment.

III. RESULTS

A. Objective Evaluation Results

This section presents the correlations between ElectrodeNet and ACE for the factors of network architecture, language, and noise type, and compares the two coding strategies with the ElectrodeNet-CS strategy in objective speech intelligibility.

1) *Network Architecture*: The scatter plots in Fig. 3 illustrate the paired objective scores of ACE and ElectrodeNet. In Fig. 3(a)–(c), each dot on a rectangular coordinate system denotes a pair of STOI scores for ACE and ElectrodeNet at $(\text{STOI}_{\text{ACE}}, \text{STOI}_{\text{ElectrodeNet}})$ for one vocoded sentence. Likewise, each dot in Fig. 3(d)–(f) denotes the NCM results estimated for one sentence at $(\text{NCM}_{\text{ACE}}, \text{NCM}_{\text{ElectrodeNet}})$. Similar trends can be noted among the DNN, CNN, and

Fig. 3. Scatter plots of STOI scores for (a) DNN, (b) CNN, and (c) LSTM networks and NCM scores for (d) DNN, (e) CNN, and (f) LSTM networks compared to ACE under SSN. The blue dots indicate scores at 5-dB SNR.

LSTM-based ElectrodeNets in both STOI and NCM scores. To clarify that the correlations are driven by the characteristics of neural networks instead of the effects of noise, the blue dots denoting the 5-dB condition indicate that the relationships are approximately linear for a single SNR level. For more informative explanations, the scatter plots and correlation scores at each SNR level are included in the Appendix. At low SNR levels, the dots representing the STOI scores are distributed farther from the origin coordinates compared to the NCM results, which suggest different properties for the two objective predictors.

The MSE, LCC, and SRCC scores in Fig. 3 reveal evidence of strong correlations between ACE and the DNN, CNN, and LSTM-based ElectrodeNets. All the MSE results based on the STOI predictor were close to 0 in a range of 0.0004–0.0007. The LCC and SRCC scores were close to the ideal result of 1 in ranges of 0.9937–0.9949 and 0.9900–0.9921, respectively. For the NCM results, the MSE scores were in a range of 0.0041–0.0066, and LCC and SRCC results were within ranges of 0.9898–0.9919 and 0.9770–0.9807, respectively. For DNN, the MSEs (0.0004 with STOI and 0.0041 with NCM) were slightly smaller than those for CNN and LSTM (0.0006–0.0007 with STOI and 0.0055–0.0066 with NCM), and the LCC (0.9949 with STOI and 0.9919 with NCM) and SRCC (0.9921 with STOI and 0.9807 with NCM) were slightly greater than those for CNN and LSTM. Although a slightly stronger relationship with ACE was observed for the DNN-based ElectrodeNet compared to the CNN and LSTM-based ElectrodeNets, the differences between the scores were quite small. Consequently, strong relationships existed between the ACE strategy and each of the DNN, CNN, and LSTM-based ElectrodeNets. Further investigations into the three types of ElectrodeNets and the ElectrodeNet-CS strategy using analysis of variance (ANOVA) are discussed in a later section.

2) *Language*: Strong relationships between the ACE and ElectrodeNet strategies for Mandarin and English speech are shown in Table III. For both data sets, the errors between ACE

TABLE III
OBJECTIVE EVALUATION RESULTS FOR MANDARIN AND ENGLISH
SPEECH MATERIALS USING DNNs WITH SSN

Predictor	Language	Speech Material	MSE	LCC	SRCC
STOI	Mandarin	TMHINT	0.0004	0.9949	0.9921
	English	TIMIT	0.0004	0.9951	0.9930
NCM	Mandarin	TMHINT	0.0041	0.9919	0.9807
	English	TIMIT	0.0031	0.9921	0.9843

TABLE IV
OBJECTIVE EVALUATION RESULTS FOR THE DNN MODEL UNDER SSN,
WHITE NOISE, STREET NOISE, AND CAFETERIA BABBLE

Predictor	Noise Type	MSE	LCC	SRCC
STOI	SSN	0.0004	0.9949	0.9921
	white noise	0.0006	0.9878	0.9870
	street noise	0.0009	0.9899	0.9837
	cafeteria babble	0.0005	0.9932	0.9887
NCM	SSN	0.0041	0.9919	0.9807
	white noise	0.0035	0.9858	0.9834
	street noise	0.0071	0.9693	0.9609
	cafeteria babble	0.0060	0.9878	0.9773

and ElectrodeNet were small and the correlations between the strategies were reasonably high. All the MSEs were close to zero (0.0004 for STOI with both languages, and 0.0031–0.0041 for NCM). The LCCs were greater than 0.99 for all conditions, and the SRCCs were above 0.99 for STOI and 0.98 for NCM. Therefore, ElectrodeNet appeared to have a high correlation to ACE with both English and Mandarin.

3) *Noise Type*: The DNN-based ElectrodeNet exhibited strong correlations with the ACE strategy in STOI and NCM scores under four types of noises as listed in Table IV. The MSE, LCC, and SRCC scores were quite close between SSN, white noise, street noise, and cafeteria babble. For STOI, the MSEs were in a range of 0.0004–0.0009, and all the LCCs and SRCCs were greater than 0.98. As to NCM, the MSEs were in a range of 0.0035–0.0071. The strongest correlations mostly occurred with SSN. The lowest correlation coefficients occurred for street noise estimated by NCM, where both LCC and SRCC were greater than 0.96. Hence, ElectrodeNet and ACE were highly correlated in speech intelligibility under all the four types of noises.

4) *ElectrodeNet-CS Strategy*: The ElectrodeNet-CS strategy was compared with the ACE strategy and the DNN, CNN, LSTM, and DNN-CS network-based ElectrodeNets for objective speech intelligibility scores. Fig. 4 shows the average STOI and NCM scores for TMHINT sentences processed by the ACE strategy, the DNN-based ElectrodeNet, and ElectrodeNet-CS using eight maxima ($N = 8$). The average scores for the CNN and LSTM networks not shown, here, were slightly lower than those for the other three strategies. A two-way ANOVA was conducted for 560 average list scores (8 lists \times 2 speakers \times 5 strategies \times 7 SNR levels) with coding strategy and SNR level as factors, and the quiet condition was considered as one of the seven SNR levels. Significant effects were observed with both coding strategy and SNR level ($p < 0.001$) for both STOI and NCM results. Post hoc analysis at each SNR level indicated that the DNN-based ElectrodeNet and ACE were distinguishable at SNRs above 10 dB for STOI and above 5 dB for NCM ($p < 0.05$). The results with the

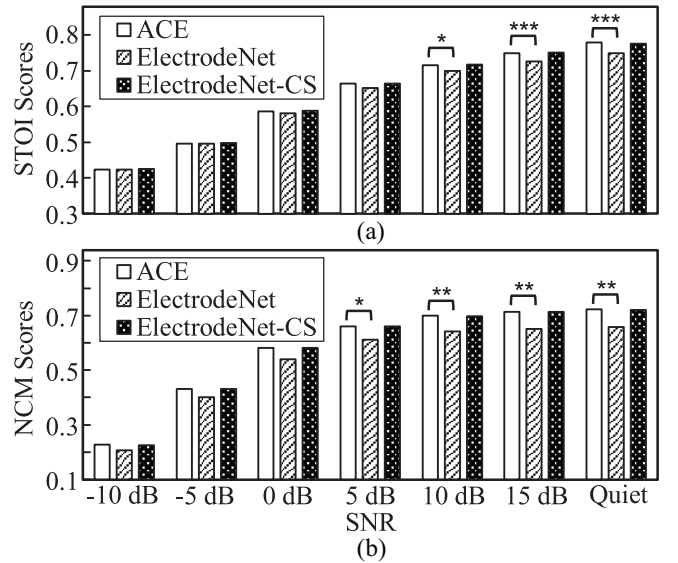

Fig. 4. Average (a) STOI scores and (b) NCM scores for vocoded TMHINT sentences processed by the ACE, ElectrodeNet, and ElectrodeNet-CS strategies with eight maxima selected ($N = 8$). Asterisks indicate significant difference to the ACE strategy with $*p \leq 0.05$, $**p \leq 0.01$, and $***p \leq 0.001$.

TABLE V
OBJECTIVE EVALUATION RESULTS FOR THE DNN-CS MODEL

Predictor	Network Maxima	MSE	LCC	SRCC
STOI	$N_{\text{topk}} = 8$	0.00001	0.9996	0.9995
	$N_{\text{topk}} = 12$	0.00001	0.9998	0.9997
NCM	$N_{\text{topk}} = 8$	0.00002	0.9996	0.9995
	$N_{\text{topk}} = 12$	0.00001	0.9998	0.9996

ElectrodeNets based on the CNN and LSTM networks were similar at SNR levels above 5 and 10 dB for STOI scores and -5 and 0 dB for NCM scores, respectively. On the other hand, the ElectrodeNet-CS strategy was similar to ACE with both STOI and NCM at all SNR levels in Fig. 4 ($p > 0.05$), and the correlations were extremely high (MSEs ≤ 0.00002 , LCCs ≥ 0.9996 , SRCC ≥ 0.9995) as listed in Table V. Surprisingly, the average STOI scores for ElectrodeNet-CS were slightly higher than the results for ACE at most SNR levels except for the quiet condition, and the differences in scores were in a small range of 0.0006–0.0021. Similar results were observed for the $N = 12$ condition, where the mean STOI scores for ElectrodeNet-CS were slightly higher than those for ACE across all SNR levels in a range of 0.0013–0.0021, except for a slightly lower score by 0.0015 in the quiet condition. For the average NCM scores, the differences between the two strategies were below 0.0024 for both $N = 8$ and $N = 12$.

B. Listening Test Results

1) *Experiment 1 (ElectrodeNet)*: The listening test results for the DNN and CNN-based ElectrodeNets in comparison to the ACE strategy are illustrated in Fig. 5. The average percent correct scores for the DNN group and the CNN group are denoted in monochrome and blue, respectively. Two-way repeated-measures (RMs) ANOVA tests were conducted for the two groups of subjects. Significant effects were noted for both factors of SNR and strategy ($p < 0.001$). Paired-samples

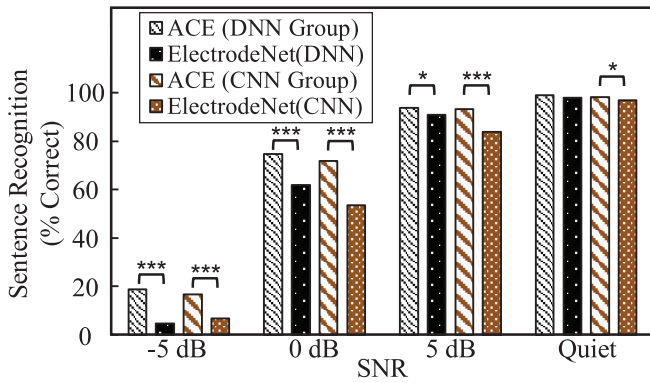

Fig. 5. Average Mandarin sentence recognition scores of two groups of 20 NH subjects for the ACE and ElectrodeNet strategies at four SNR levels ($N = 12$). The DNN group participated listening tests for the ACE strategy and the DNN-based ElectrodeNet (in monochrome), and the CNN group for ACE and the CNN-based ElectrodeNet (in brown). Asterisks indicate significant differences with $*p \leq 0.05$ and $***p \leq 0.001$. No statistical difference was observed between ACE and the DNN-based ElectrodeNet in the quiet condition.

Fig. 6. Average Mandarin sentence recognition scores of 20 NH subjects for the ACE and ElectrodeNet-CS strategies with $N = 8$ (in monochrome) and $N = 12$ (in blue) at four SNR levels. No significant difference was observed between the two strategies for each N and SNR level ($p > 0.05$).

T -tests indicated that the DNN-based ElectrodeNet performed similarly to the ACE strategy in the quiet condition ($p > 0.05$), while the results for the other conditions showed slightly lower speech intelligibility for the DNN and CNN-based ElectrodeNets compared to ACE ($p < 0.05$). At less noisy SNR levels, the differences to the ACE strategy were 3.0% (5 dB) and 1.0% (quiet) for the DNN-based ElectrodeNet, and 9.5% (5 dB) and 1.3% (quiet) for the CNN counterpart. At -5 and 0 dB, the ACE strategy yielded speech intelligibility scores 10.0-18.3% higher than those for ElectrodeNets. It appears that only the DNN-based ElectrodeNet modeled the ACE strategy well in the quiet condition.

2) *Experiment 2 (ElectrodeNet-CS)*: The sentence recognition results for ACE and ElectrodeNet-CS with 8 and 12 maxima at four SNR levels are shown in Fig. 6. For each maxima N , the two-way RM ANOVA showed a significant effect with SNR ($p < 0.001$), but no significant effect with coding strategy ($p > 0.05$). Paired-samples T -tests for each SNR level and maxima N indicated no significant difference between the two strategies in all comparisons ($p > 0.05$). At -5 dB SNR, the average percent correct scores of the ElectrodeNet-CS strategy, 13.6% for $N = 8$ and 20.8% for

$N = 12$, were slightly higher than those of the ACE strategy, 13.0% and 17.0%, respectively. For the 0-dB SNR, the mean recognition scores for ACE and ElectrodeNet-CS were 72.1% and 68.2% for $N = 8$, and 75.2% and 74.2% for $N = 12$, respectively. For the 5-dB SNR and the quiet condition, the average results for ACE and ElectrodeNet-CS were similar for both N maxima, and the differences were within 1.47%. The average score for ElectrodeNet-CS with $N = 12$ in the quiet condition was 99.1% and slightly higher than the 98.5% score for ACE. The experimental and statistical analysis results implied that the ElectrodeNet-CS strategy performed similarly to ACE with Mandarin speech.

IV. DISCUSSION

A. ElectrodeNet

The strong correlations between ElectrodeNet and the ACE strategy in STOI and NCM scores suggested that a deep-learning-based coding strategy is capable of producing stimuli with speech intelligibility closely related to that for ACE. These close relationships held for the three experimental factors of network architecture, data set language, and noise type. By inspecting the architecture of neural networks, the L-to-M envelope detection of ACE can be considered as a special case of a fully connected network with fixed weights, no hidden layers, no biases, and bypassed activation functions. In other words, the dense layers in the DNN, CNN, and LSTM models can be regarded as generalized forms of ACE's envelope detection using nonlinear operations. Consequently, the DNN-based ElectrodeNet exhibited a slightly stronger relationship with ACE, possibly due to its closer network architecture compared to CNN and LSTM structures. In this study, neural networks were trained by a single frame at each time. If more temporal and spectral information was referenced during training, other networks with more advanced architecture, such as CNN and LSTM, may take advantage of their capabilities in model framework. In terms of the data set language factor, the DNN-based ElectrodeNet performed fairly well in representing Mandarin and English speech as analogous forms of ACE vocoded speech with TMHINT and TIMIT sentences. For the factor of noise type, the correlations between the two strategies in STOI and NCM scores were generally stronger for SSN due to its closer resemblance to the training speech materials compared to white noise, street noise, and cafeteria babble.

Although the STOI and NCM scores between ElectrodeNet and ACE showed "strong correlations," they were found to be "significantly different" in ANOVA analysis. The results of analyzing identical data using the two different types of statistical measurements appeared to be different, but these discrepancies may still be explained. The MSE, LCC, and SRCC scores measured the strength of relationship between the two strategies in STOI and NCM scores. Since the neural networks mimicked the envelope detection function, the outputs of ElectrodeNet were dependent to those of ACE with some relationships, which were quantified as strong correlations in this study. ANOVA, however, compares the means of different groups of STOI and NCM scores processed by different coding strategies. Based on supervised learning, the

TABLE VI
AVERAGE STOI SCORES FOR THE DNN-CS AND DNN-CS_{VT}
MODELS WITH DIFFERENT TRAINING TARGETS (N = 8)

SNR (dB)	ACE	DNN	DNN-CS		DNN-CS _{VT}	
			Target: M	N-of-M	M	N-of-M
-10	0.4229	0.4234	0.4245	0.4225	0.4297	0.4166
0	0.5868	0.5810	0.5884	0.5823	0.5899	0.5614
10	0.7163	0.7000	0.7173	0.7011	0.7213	0.6756
Quiet	0.7786	0.7495	0.7766	0.7505	0.7837	0.7313

Note: The DNN-CS_{VT} model uses the vanilla topk (VT) function for CS.

DNN network of ElectroNet learned the process of the L-to-M envelope detection, but the network output envelopes may not always closely follow the those of the ACE strategy. Using network output as envelopes could impact the subsequent N-of-M selection, potentially leading to reduced intelligibility. For example, the electrodiagram in Fig. 2(c) showed that the DNN-based ElectroNet generated a few undesired high-frequency pulses as interferences and, hence, may have negative effects on the performance. Therefore, ElectroNet-CS was proposed to investigate whether including a CS layer would improve ElectroNet to perform more closely to the ACE strategy.

B. ElectroNet-CS

Both the objective and subjective evaluations showed that the ElectroNet-CS strategy had similar or even slightly higher average scores than ACE under certain conditions. The superior results of the DNN-CS model for ElectroNet-CS compared to the DNN-based ElectroNet were consistent with the electrodiagrams in Fig. 2. Compared to the conventional N-of-M process of ElectroNet, the custom topk layer of the ElectroNet-CS strategy, took part in network training and resulted in a more similar modeling of ACE's channel envelopes, particularly the stimuli important for speech recognition below approximately 2 kHz (Channel 12).

In this study, one aspect that required clarification was the use of a different training target when comparing the signal processing architectures of ACE and ElectroNet-CS in Fig. 1. For a match to the CS output of the ACE strategy, the N-of-M patterns were adopted as the training target of the DNN-CS model. Table VI shows that the DNN-CS network trained using the N-of-M selection output of the ACE strategy (N = 8) was with lower STOI scores than using the entire spectrum of M-channel envelopes. With the N-of-M target, the neural network was trained to prioritize N channels with positive values, but the remaining M-N channels were trained to converge toward zeros. When a network learned to produce zeros in some channels, the resulting stimuli became sparser and the corresponding STOI scores decreased. The use of the entire M-channel target for training, however, determined the CS output based on full spectral contents instead of just the N maximal envelopes. Therefore, in this study, the M-channel data was used to train the DNN-CS model for its slightly higher performance compared to the N-of-M patterns.

Another aspect to be clarified was the effectiveness of using PyTorch's topk function directly in the CS layer, referred to as vanilla topk (VT), as opposed to a customized topk. The network with the VT function, DNN-CS_{VT}, produced slightly higher STOI scores, 0.4297 (-10 dB), 0.5899 (0 dB),

0.7213 (10 dB), and 0.7837 (quiet), compared to ACE and the DNN-CS model as listed in Table VI. However, the NCM scores for DNN-CS_{VT} were lower than those for ACE scores by a range of 0.02–0.03, compared to a smaller range of 0.001–0.0024 for the DNN-CS model. Furthermore, the DNN-CS_{VT} strategy switched off some channels while minimizing the loss. For example, the DNN-CS_{VT} model with $N_{\text{topk}} = 12$ bypassed Channels 18 (4375 Hz), 19 (5000 Hz), and 21 (6500 Hz), while the model with $N_{\text{topk}} = 8$ even bypassed six channels. Although disabling high-frequency channels may increase STOI scores due to the greater relevance of low-to-mid frequency components to speech perception, the seemingly random deactivation of electrodes was problematic. In the case of training the DNN-CS_{VT} network with the N-of-M target, sparser output resulted in lower STOI scores compared to all other conditions shown in Table VI, suggesting a lack of robustness in the network's structure. Owing to the aforementioned limitations, a custom topk layer was used in ElectroNet-CS, while the findings with the DNN-CS_{VT} network presented herein may still offer some insights into related CI research.

In contrast to the DNN and DNN-CS_{VT} models, the use of the DNN-CS network enabled ElectroNet-CS to achieve success in both compatibility and performance with the ACE strategy. In the DNN-CS model, the custom topk layer not only learned to minimize the loss with the M-channel envelopes by selecting N_{topk} maxima and suppressing the other positive network outputs but also adjusted the remaining negative outputs with high loss to be non-negative during training. As a result, ElectroNet-CS increased the weights important to speech features, weakened connections less relevant to the loss function, preserved the N-of-M compatible pattern without bypassing any channels, and produced the specified number of maxima ($N_{\text{CS}} \leq N_{\text{topk}}$). With the special CS design, both the objective and subjective evaluation results showed that the ElectroNet-CS strategy had similar or even slightly higher average scores than ACE in some conditions. Specifically, the higher mean STOI scores across all noisy conditions and the higher mean sentence recognition results for at -5-dB SNR are worthy to be noticed. The inspiring findings in ElectroNet-CS encouraged further exploration of the mechanisms of deep-learning-based envelope detection and CS. Furthermore, the flexibility of network architecture to incorporate new functions is an important strength of deep learning for future CI research.

C. General Discussion

The utilization of deep learning in CI coding strategy has provided new insights into the "AI + CI" field. AI not only transforms hearing healthcare and research [11] but also has great potential to break through the present limitations with CI coding strategy. With more advanced network architectures and training methods, deep-learning-based coding strategies may outperform the present coding strategies. Moreover, deep learning can be considered not as a competitor, but as a collaborator in complement to traditional signal processing approaches. Researchers may use deep learning not only as a tool to resolve problems but also as an approach to explore undiscovered knowledge. Based on the present findings contributed by

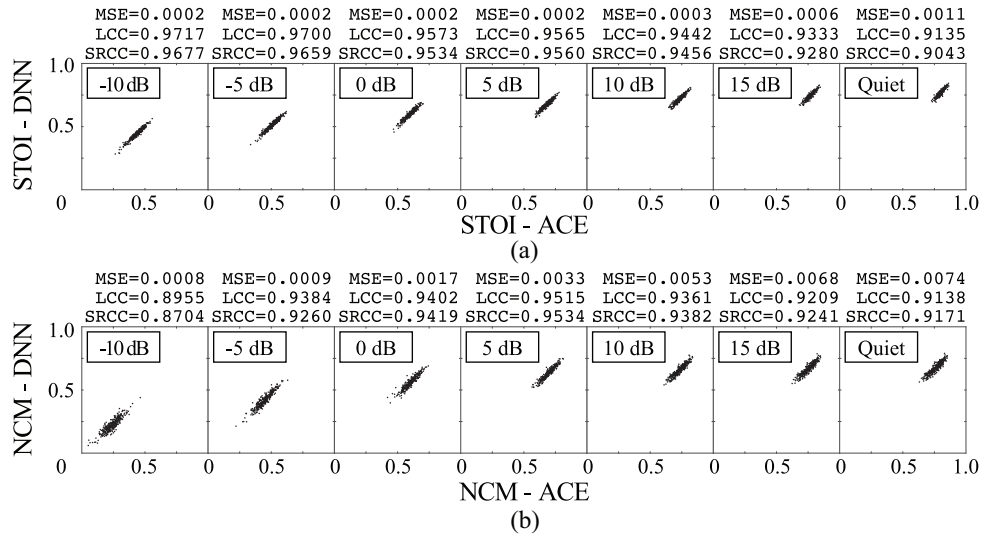

Fig. 7. Scatter plots of (a) STOI and (b) NCM scores at different SNR levels for the ACE strategy and the DNN-based ElectrodeNet strategy with $N = 12$.

numerous experts, it is promising to see the potential for deep learning to benefit CI users in the future.

On the journey toward a deep-learning-based sound coding strategy, issues of complexity, latency, safety, and ethics are important for researchers. With the advances in calculation speed and energy efficiency, computational complexity is becoming less of a primary issue in hardware design, especially, for compressed pretrained network models on devices. Using the analogy of commercial hearing aids with DNN models [22] and complicated ASR chips [83], the innovation for CI coding strategy is expected to be in a similar transitional process. For hearing assistive devices, latency is another critical challenge, and real-time inference with compact models is an important direction for investigation [49]. As a neural prosthetic device is implanted in the human body, thorough considerations of safety and ethics are essential for deep learning driven algorithms. For example, the maxima selection, presentation level, and pulse patterns determined using deep learning must comply with the safety limits to prevent biological damage and uncomfortable overstimulations [84]. In addition, AI raises ethical issues, such as privacy concerns in collecting user data for retraining models and further research. Equal and effective communication is required between researchers, practitioners, and CI users in collecting personal information and expectations in AI technologies. Present guidelines related to research ethics and IRB approvals may need to be renovated to reinforce moral values, considerations, and regulations for researchers and institutes in the development of deep-learning-based neural prosthetic devices [85], [86].

More investigations on deep-learning-based coding strategies are necessary. The present study focused on mimicking the core processing of the ACE strategy using neural networks and, hence, did not consider using noisy, reverberant, and mixed speech as input data to train the network model. It is planned to build a more powerful neural-based CI system, which can flexibly combine ElectrodeNet with various speech preprocessing, such as speech denoising, dereverberation, and speech separation, using more advanced network architectures and training methods, such as end-to-end learning

and joint-training. Additional multimodal information, such as contralateral sounds, visual cues, tactile vibrations, and auditory and vestibular responses, may also be processed in the same system [29], [87], [88], [89]. Therefore, expanding deep learning modules is potential to provide breakthroughs in CI signal processing and there is a great demand for further research by conducting more simulations and clinical experiments with CI listeners. The innovation for ElectrodeNet is on-going to make some differences to the AI + CI and other relevant fields.

V. CONCLUSION

Investigations on ElectrodeNet revealed that deep-learning-based sound coding strategies may have similar or even slightly higher average speech intelligibility compared to the ACE strategy. By replacing the conventional envelope detection and CS stages using a neural network, the ElectrodeNet and ElectrodeNet-CS strategies performed satisfactorily.

- 1) Strong correlations exhibited between ACE and the DNN, CNN, and LSTM-based ElectrodeNets as indicated by the MSE, LCC, and SRCC.
- 2) Strong correlations exhibited between ACE and the DNN-based ElectrodeNet for both TMHINT and TIMIT data sets, and for the four types of noises.
- 3) The ElectrodeNet-CS strategy was capable of producing N-of-M compatible electrode stimulation patterns.
- 4) After combining the CS function, ElectrodeNet-CS performed similarly or slightly above average in STOI and sentence recognition results compared to ACE.

The findings suggest the substantial feasibility of using ElectrodeNet as an alternative to traditional coding strategies and its flexible network architecture to create new networks, such as ElectrodeNet-CS, to achieve higher performance. This study provides some insights and research directions toward the inevitable trend of the “AI + CI” revolution.

APPENDIX

To demonstrate the correlations between the ACE strategy and the DNN-based ElectrodeNet in STOI and NCM scores

for each SNR level, Fig. 7 shows their scatter plots and correlation scores. All dots in each subfigure are arranged close to a positive linear relationship. The correlation scores indicate strong correlations between the two strategies (MSEs ≤ 0.0011 , LCCs ≥ 0.9135 , SRCCs ≥ 0.9043 for STOI, and MSEs ≤ 0.0074 , LCCs ≥ 0.8955 , SRCCs ≥ 0.8704 for NCM). The MSEs are slightly larger than those computed across all SNR levels in Fig. 3(a) and (d) (MSEs = 0.0004 for STOI and MSE = 0.0041 for NCM), where correlation scores may be driven both by the characters of neural networks and the SNR levels. The correlation coefficients for each SNR level are slightly smaller than those in Fig. 3(a) and (d) (LCC = 0.9949 and SRCC = 0.9921 for STOI, and LCC = 0.9919, SRCC = 0.9807 for NCM). Although the scores computed across different SNR level slightly enhance correlation scores, Fig. 7 shows that strong correlations between ACE and ElectrodeNet are still present at single SNR levels.
