**ABSTRACT** Herein, highly stable nitrogen (N) doped amorphous indium gallium tin oxide (a-IGTO) thin-film transistors (TFTs) are prepared and the effects of N-doping are investigated. Compared with undoped a-IGTO TFTs, a-IGTO TFTs with 6 min N plasma treatment exhibit superior bias stress stability and a threshold voltages ( $V_{th}$ ) closer to 0 V with almost no decline in mobility. In particular, the positive/negative bias stress threshold shift of N-doped a-IGTO TFTs is substantially reduced in both dark and light environment. The X-ray photoelectron spectroscopy analysis (XPS) and low frequency noise (LFN) are employed to study the mechanism of N-doping in a-IGTO TFTs. The XPS results indicate that appropriate amount of N-doping could enhance the bias stress stability and control the  $V_{th}$  efficiently by passivating the defects such as oxygen vacancy in a-IGTO films. The LFN results illustrate that the average interfacial trap density could be reduced by N-doping. Overall, the strategy presented here is effective for preparing a-IGTO TFTs with enhanced stability for potential applications in future optoelectronic displays.

**INDEX TERMS** Amorphous indium gallium tin oxide (a-IGTO), thin-film transistors (TFTs), N doping, bias stress stability, low frequency noise (LFN).

## I. INTRODUCTION

Zinc oxide (ZnO) based amorphous oxide semiconductor (AOS) thin film transistors (TFTs), such as amorphous indium zinc oxide (a-IZO) and indium gallium zinc oxide (a-IGZO) TFT, have been widely used in flat panel displays because of their excellent electrical performance and low manufacturing cost during past decade [1], [2], [3]. However, the inferior bias stress stability and low field effect mobility (usually  $1\sim 10$  cm<sup>2</sup>/V·s) of these ZnO-based TFTs usually limit their practical applications for ultra-high resolution and large area displays [4]. Recently, amorphous indium gallium tin oxide (a-IGTO) as one of the most powerful alternative and complementary materials to a-IGZO has attracted more and more attention [5], [6], [7]. By contrast, a-IGTO TFT has a higher mobility, which is due to the s orbital overlap of In and Sn is greater than the overlap of In and Zn, and this finally enhances the permeation conduction path

[8], [9], [10]. In addition, the oxygen bonding energy of Sn (528 kJ/mol) is stronger than that of Zn (250 kJ/mol), which could further improve device stability.

As reported in the literatures, a-IGTO TFTs have been well prepared using various fabrication methods, such as atomic layer deposition, solution process, and magnetron sputtering [6], [7], [11]. All these devices demonstrate excellent electrical performance with a relatively low preparation temperature. However, the bias stress stability of a-IGTO TFTs still needs to be further enhanced, especially the stability in a light environment. Meanwhile, the significant deviation of the threshold voltages ( $V_{th}$ ) from 0 V is also a problem for a-IGTO TFTs in low power consumption applications. Hence, a method that can control the  $V_{th}$  shift and enhance bias stress stability without damaging mobility needs to be proposed. Plasma treatment has been demonstrated as an efficient strategy to modulate the carrier concentration and reduce

the defect states associated with oxygen vacancies ( $V_O$ ) in ZnO-based AOS TFTs [12]. Oxygen (O) plasma has been proved to be effective for reducing  $V_O$  in a-IGTO TFTs [13]. However, it will significantly reduce the  $V_O$  concentration and increase the surface roughness of the film, resulting in a sharp decline in performance [14]. Nitrogen (N) has been confirmed to serve as both an acceptor and a defect binder in a-IGZO TFTs to improve the bias stress stability of a-IGZO TFTs [15], [16]. Compared with O plasma, N plasma is considered more friendly to improve the thin-film properties [14]. In view of this, N plasma treatment is an ideal strategy to address the issues of a-IGTO TFTs.

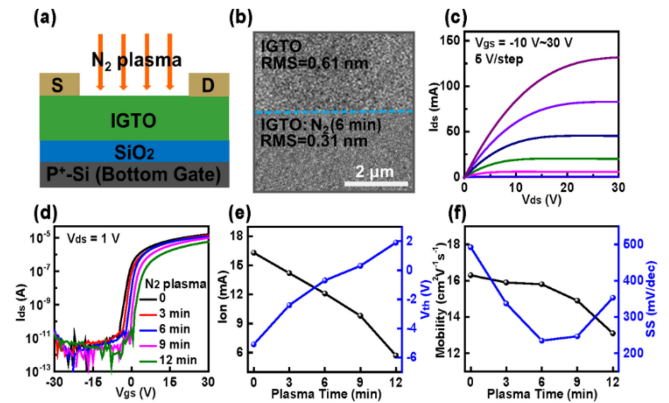

Herein, we studied the a-IGTO TFTs with different N-doping levels via a magnetron sputtering and N plasma treatment. With appropriate N-doping, the reliability of a-IGTO TFTs are greatly improved both in dark and light environment. Simultaneously, the  $V_{th}$  shifted to 0 V alone with a relative undamaged field-effect mobility ( $\mu_{FE}$ ). To understand the charge trap mechanisms of N in a-IGTO TFTs, X-ray photoelectron spectroscopy (XPS) and low-frequency noise (LFN) analyses are carried out. The XPS results indicate that N plasma treatment could suppresses the formation of excess  $V_O$  effectively. The LFN result demonstrates that N plasma treatment could reduce the interface trap density in a-IGTO TFTs. All these results show that N-doping could enhance the stability and control the  $V_{th}$  of a-IGTO TFTs by passivating the defects and improving interface quality.

## II. DEVICE STRUCTURE AND EXPERIMENTAL

The schematic view of the N-doped a-IGTO TFTs fabricated and characterized in this study is depicted in Fig. 1(a). First, 20 nm a-IGTO thin film is deposited using radio frequency (RF) magnetron sputtering on a 100 nm  $\text{SiO}_2$  coated p<sup>+</sup>-Si substrate with a IGTO ceramic target ( $\text{In}_2\text{O}_3:\text{Ga}_2\text{O}_3:\text{SnO}_2 = 7:2:1$  mol%). During the deposition process, the RF power was set as 40 W, the substrate pressure was below  $3 \times 10^{-4}$  Pa, the Ar gas flow rate was 15 sccm, the sputtering chamber pressure was maintained at 0.8 Pa, and the substrate temperature was fixed at 100 °C. After the deposition, the a-IGTO thin film is directly treated in the aforementioned RF magnetron sputtering system using  $\text{N}_2$  plasma with a gas mixing ratio of  $\text{N}_2:\text{Ar} = 20:40$ . The plasma treatment times are 0, 3, 6, 9, and 12 min, respectively. Finally, 100 nm Al source/drain electrodes are prepared using a direct current sputtering process. The a-IGTO thin film and Al electrodes are patterned with matching metal shadow masks, and the channel length ( $L$ ) and width ( $W$ ) are designed to be 120  $\mu\text{m}$  and 150  $\mu\text{m}$ , respectively.

## III. CHARACTERIZATION AND DISCUSSION

All the electrical performance characterizations of the N-doped a-IGTO TFTs are performed under ambient conditions. An Agilent B2912 analyzer with a Lakeshore probe station is used for the electrical measurements, and an

**FIGURE 1.** (a) Schematic view of the N-doped a-IGTO TFTs. (b) AFM images of a-IGTO TFTs with 0 and 6 min N plasma treatment. (c) Typical output characteristics of a-IGTO TFTs with 6 min N plasma treatment. (d) Typical transfer characteristics (with  $I_{ds}$  plotted logarithmically) of N-doped a-IGTO TFTs with different N plasma treatment time at  $V_{ds} = 1$  V. (e) and (f)  $I_{on}$ ,  $V_{th}$ ,  $\mu_{FE}$ , and SS of N-doped a-IGTO TFTs with different N plasma treatment time.

NC300L LFN analyzer is employed for the LFN measurements.

To evaluate the effect of N plasma treatment to the film surface roughness, the surface topographies of the a-IGTO thin films with different plasma treatment times were measured by an atomic force microscope (AFM). The AFM images for 0 and 6 min are shown in Fig. 1(b). The results show that the N plasma treatment has an effect on the surface roughness of the a-IGTO films. The root means square roughness (RMS) of undoped a-IGTO films is 0.61 nm, and the RMS is reduced to 0.31 nm after N-doping. A rough interface usually appears as deep valleys that act as carrier traps and scattering centers [17]. A smaller RMS result indicates that N plasma treatment could weaken the surface scattering effect and is benefits to the carrier mobility and contact resistance between the source-drain electrode and the a-IGTO thin film. Unfortunately, an excessive treatment time will introduce physical damage and interface defects to the film surface and increase the surface roughness [12].

Fig. 1(c) exhibits the output characteristic of a-IGTO TFT with 6 min N plasma treatment. The gate-source voltage ( $V_{gs}$ ) changes from  $-10$  to  $30$  V with a  $5$  V step. The saturation and conspicuous pinch-off characteristics indicate that the channel layer can be significantly modulated by the gate potential. Besides, the gate-drain current ( $I_{ds}$ ) increases linearly in the small gate drain voltage ( $V_{ds}$ ) region illustrates that the channel layer and the source/drain are ohmic contact [18]. The transfer characteristic curves of a-IGTO TFTs with N plasma treatment times of 0, 3, 6, 9, and 12 min at  $V_{ds}$  is  $1$  V and the  $V_{gs}$  is swept from  $-30$  to  $30$  V is displayed in Fig. 1(d). All the transfer curves show a typical n-type characteristics with an on/off ratio of  $10^7$ . To better characterize the effect of N-doping in a-IGTO TFTs, the key electrical performance parameters of the device are extracted. Fig. 1(e) shows the N-doping effect on ON-state channel current ( $I_{on}$ ) and  $V_{th}$  of the N-doped

a-IGTO TFTs. The  $V_{th}$ , which is extracted by the horizontal intercept of the linear region of the  $I_{ds}^{1/2}$  versus  $V_{ds}$  plot, shifts to the right from  $-5.1$  to  $1.9$  V as the N plasma treatment time increases from 0 to 12 min. Meanwhile, the  $I_{on}$  decreases as N plasma treatment time increases. These results demonstrate that N-doping is a p-type doping for a-IGTO TFTs. The positive shift of  $V_{th}$  and the reduction of  $I_{on}$  are interpreted to be associated with the decrease of electron concentration ( $n_e$ ) [19]. The  $n_e$  can be calculated using the following equation [20], [21]:

$$n_e = \frac{I_{on}L}{qSV_{ds}\mu_{FE}}$$

where  $S$  is the cross-sectional area of the active layer. The  $n_e$  value of N plasma treatment time increased from 0 to 12 min are decreased from  $2.5 \times 10^{18}$  to  $0.9 \times 10^{18}$   $\text{cm}^{-3}$ , respectively. In general, the  $V_O$  supply the electrons [12]. Thus, the decrease of  $n_e$  also proved that N doping inhibits the generation of  $V_O$  in a-IGTO TFTs.

The  $\mu_{FE}$  and subthreshold swing ( $SS$ ) as a function of N-doping is plotted in Fig. 1(f). The value of  $\mu_{FE}$  can be calculated by the following equation [22]:

$$\mu_{FE} = \frac{g_m L}{WC_i V_{ds}}$$

where  $C_i$  is the capacitance per unit area of  $\text{SiO}_2$ ,  $g_m$  is the transconductance and is obtained by the equation of  $g_m = dI_{ds}/dV_{gs}$ . The resulting  $\mu_{FE}$  for 0, 3, 6, 9, and 12 min N plasma treatment time are 16.3, 15.9, 15.8, 14.9, and 13.1  $\text{cm}^2/\text{V}\cdot\text{s}$ , correspondingly. It is delightful that although  $n_e$  is obviously decreased as the N plasma time increase, the  $\mu_{FE}$  is slightly decreased. That is mainly because the N-doping could inhibit the generation of  $V_O$  as discussed in the  $n_e$ , and the  $V_O$  usually act as electron traps in the TFTs [23], [24].

To verify the N plasma treatment could reduce charge traps,  $SS$  of these TFTs are also extracted from the formula:  $SS = dV_{gs}/d\log I_{ds}$ . In general, the  $SS$  value is related to the interface trap density ( $D_{it}$ ) between the a-IGTO channel layer and the  $\text{SiO}_2$ . The  $D_{it}$  could be estimated based on the following equation [25]:

$$D_{it} = \left( \frac{qSS}{k_B T \ln 10} - 1 \right) \frac{C_i}{q}$$

where  $T$  is the temperature during measurements and  $k_B$  is Boltzmann's constant. It could be seen that the a-IGTO TFT with 6 min N plasma treatment has a minimum  $SS$  compared with other TFTs, with the resulting  $D_{it}$  of  $0.76 \times 10^{12}$   $\text{cm}^{-2}\text{eV}^{-1}$ , which is superior to that of the undoped a-IGTO TFT with a value of  $1.33 \times 10^{12}$   $\text{cm}^{-2}\text{eV}^{-1}$ . These results demonstrate that the N-doping can also reduce  $D_{it}$  and improve the interface quality between the a-IGTO and  $\text{SiO}_2$ .

The charge trapping in the gate dielectric and/or at the channel/dielectric interface would cause a  $V_{th}$  shift ( $\Delta V_{th}$ ) under positive/negative bias voltage stress [26]. To demonstrate the inhibition of defects by N-doping, the bias

FIGURE 2. (a)-(d) The PBS, PBIS, NBS, and NBIS of undoped a-IGTO TFTs at  $V_{gs} = \pm 10$  V and stress duration of 3600 s.

stress stabilities of a-IGTO TFTs with 0 and 6 min N plasma treatment at  $V_{gs} = 10$  V and  $-10$  V, under dark and light environments, and stress duration of 3600 s are investigated.

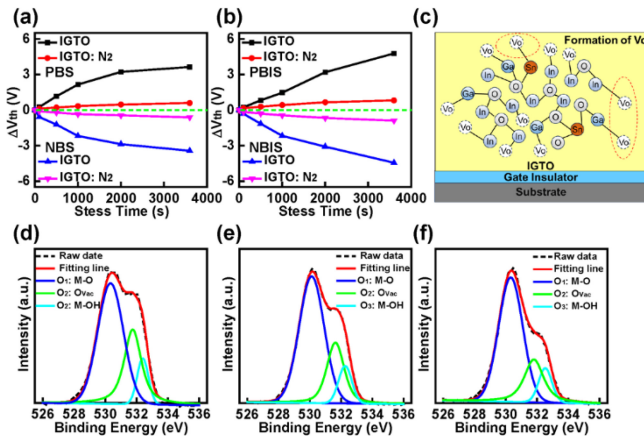

Fig. 2(a)-(d) presents the positive gate-bias stress (PBS), light illumination positive gate-bias stress (PBIS), negative gate-bias stress (NBS), and light illumination negative gate-bias stress (NBIS) of undoped a-IGTO TFT, respectively. The undoped a-IGTO TFT shows  $\Delta V_{th}$  of 3.63 V for PBS and  $-3.44$  V for NBS, as shown in Fig. 2(a) and (c). When introducing the illumination condition, the gate-bias stress stability becomes worse and the  $\Delta V_{th}$  becomes 4.77 V for PBIS and  $-4.45$  V for NBIS, as plotted in Fig. 2(b)-(d). The increase in  $\Delta V_{th}$  mainly comes from the photo-desorption of oxygen-related species under light illumination [27]. Meanwhile, the gate-bias stress of a-IGTO TFTs with 6 min N plasma treatment is depicted in Fig. 3(a)-(d). Both under dark and light condition, the N-doped a-IGTO TFT exhibits a small  $\Delta V_{th}$  for PBS (0.59 V), NBS ( $-0.62$  V), PBIS (0.81 V), and NBIS ( $-0.9$  V) compared with the undoped a-IGTO TFT.

The  $\Delta V_{th}$  under gate-bias stress could be attributed to temporal charge trapping in the channel region and/or at the interface and the charge trap state results from the  $V_O$  has been confirmed [28]. The detailed plots of  $V_{th}$  shift versus stress time of a-IGTO TFTs with 0 and 6 min N plasma treatment are depicted in Fig. 4(a)-(b) and a significant decrease of  $\Delta V_{th}$  can be seen in N-doped a-IGTO TFT. This result indicates that the N-doping could enhance bias stress stability of the a-IGTO TFT. In other words, with appropriate N-doping, the generation of  $V_O$  could be effectively suppressed, and finally cause a small  $\Delta V_{th}$  and enhancement in bias stress stability for a-IGTO TFT. This conclusion is consistent with the previous results and

**FIGURE 3.** (a)-(d) The PBS, PBIS, NBS, and NBIS of a-IGTO TFTs with 6 min N plasma treatment at  $V_{gs} = \pm 10$  V and stress duration of 3600 s.

**FIGURE 4.** (a) The detailed plot of  $\Delta V_{th}$  versus stress time of the a-IGZO with 0 and 6 min N plasma treatment under PBS and NBS. (b) The detailed plot of  $\Delta V_{th}$  versus stress time of the a-IGZO with 0 and 6 min N plasma treatment under PBIS and NBIS. (c) Schematic view of interfaces trap sites and  $V_O$  defect states in the a-IGTO TFT. (d)-(f) O 1s XPS spectra of the a-IGTO thin film with 0, 6, and 12 min N plasma treatment.

discussions about the  $n_e$  and  $D_{it}$ . The N-doped a-IGTO TFT obtains a better gate-bias stress stability while compared with undoped a-IGZO TFT and the relevant reason is that the traps associated with  $V_O$  are constantly suppressed by the N-doping.

Fig. 4(c) depicts the interfaces trap sites and  $V_O$  defect states of the a-IGTO thin films. The doping principle lies that the N would replace these  $V_O$  and form N-metal bond by attaching to metal ions after N plasma treatment [12], [14], [29]. To verify the detailed principle of N-doping, the O 1s and N 1s bonding properties of N-doped a-IGTO thin films are analyzed by XPS. The O 1s spectra of a-IGTO TFT with 0, 6, and 12 min N plasma

**FIGURE 5.** (a)-(d) N 1s XPS spectra of the a-IGTO thin film with 0, 6, 9, and 12 min N plasma treatment.

treatment are carefully deconvoluted into three different peaks, centered at  $529.9 \pm 0.1$ ,  $530.7 \pm 0.1$ , and  $531.9 \pm 0.1$  eV, respectively, as shown in Fig. 4(d)-(f) [30]. The area of  $O_2 = (O_2/O_1 + O_2 + O_3)$  decreases from 32.6% to 26.7% to 21.4% as the N plasma treatment time increases from 0 to 6 to 12 min, indicating that the  $V_O$  are reduced by the N plasma treatment. This result illustrates the N-doping could significantly reduce  $V_O$  defect states in the active channel layer of the a-IGTO thin films and improve the bias stress stability, which is consistent with the above discussion. The experimental curve of the N 1s XPS spectra of a-IGTO thin films with 0, 6, 9, and 12 min N plasma treatment are exhibited in Fig. 5(a)-(d). As the N plasma time is increased to 6 and 9 min, the peak shift to higher energy. Besides, the N-Ga peak start to appear and gradually increased [16]. When the N plasma time increased to 12 min, the peak of  $\gamma$ -N<sub>2</sub> (relating to adsorbed nitrogen molecules or impurities) is appear, suggesting that there are more defects (non-reacted N<sub>2</sub> molecules) introduced into a-IGTO films if too many nitrogen atoms were doped [31]. The N 1s XPS spectra indicates N is successfully doped in a-IGTO thin films.

To further verify the impacts of N plasma treatment to the trap density, the LFN measurement is carried out for the a-IGTO TFTs with 0, 6, and 12 min N plasma treatment. Fig. 6(a) shows the relationship between normalized drain-current noise spectral densities ( $S_{ID}/I_D^2$ ) and frequency ( $f$ ) of a-IGTO TFT with 6 min N plasma treatment. It is apparent that all the curves fit classical  $1/f$  noise model very well when the  $(V_{gs}-V_{th})$  ranging from 1 to 5 V and the  $f$  ranging from 1 to 1000 Hz [32]. Subsequently, the LFN measurements of a-IGTO TFTs with 0, 6, and 12 min N plasma treatment are

**FIGURE 6.** (a) Typically normalized LFN spectrum of the a-IGTO TFTs with 6 min N plasma treatment at  $V_{ds} = 1$  V and  $(V_{gs} - V_{th})$  ranging from 1 to 5 V. (b) Typically normalized LFN spectrum of the a-IGTO TFTs with 0, 6, and 12 min N plasma treatment at  $(V_{gs} - V_{th}) = 3$  V and  $V_{ds} = 1$  V. (c) Normalized  $S_{ID}/I_D^2$  as a function of  $(V_{gs} - V_{th})$  log-log plots of the a-IGTO TFTs with 0, 6, and 12 min N plasma treatment at  $f = 40$  Hz and  $V_{ds} = 1$  V. (d) The calculated  $N_{it}$  as a function of different over drive gate voltage.

conducted to make a comparison at  $(V_{gs} - V_{th}) = 3$  V and  $V_{ds} = 1$  V, as shown in Fig. 6(b). In general, carrier number fluctuation ( $\Delta N$ ) and correlated mobility fluctuation ( $\Delta\mu$ ) are used to explain the origin of the  $1/f$  noise [33]. The  $\Delta N$  theory explains the origin of  $1/f$  noise as the generation-recombination noise in the electron transitions between the conduction band of the channel material and the traps in the oxide layer. While the  $\Delta\mu$  theory regards the fluctuations in mobility of free carriers in conducting channel as the origin of  $1/f$  noise [33], [34]. The relationship between  $S_{ID}/I_D^2$  and  $(V_{gs} - V_{th})$  is fitted in Fig. 6(c) at  $V_{ds} = 1$  V and  $f = 40$  Hz. All three TFTs show an approximate slope value of  $-2$ , indicating the origin of  $1/f$  noise is caused by  $\Delta N$  theory [30]. According to the  $1/f$  noise model, the average interfacial trap density ( $N_{it}$ ) within the gate oxide could be estimated by the following equation [35]:

$$N_{it} = \frac{S_{ID}C_i^2WLf(V_{gs} - V_{th})\gamma}{q^2k_B T I_D^2}$$

where  $\gamma$  is  $10^8$  cm $^{-1}$  for the Si-SiO $_2$  system [32]. The calculated  $N_{it}$  value of a-IGTO TFTs with 0, 6, and 12 min N plasma treatment at  $f = 40$  Hz and  $(V_{gs} - V_{th})$  changes from 1 to 5 V is shown in Fig. 6(d). The curve reflects the approximately uniform oxide trap distribution in each device. The  $N_{it}$  are calculated to be  $1.8 \times 10^{20}$ ,  $8.7 \times 10^{18}$ , and  $5.66 \times 10^{19}$  for 0, 6, and 12 min N plasma treated a-IGTO TFTs, respectively. This result is consistent with the above discussion about  $D_{it}$  estimated from SS. It further proves that moderate N-doping could reduce defects in the channel

layer, while excessive N plasma treatment will introduce additional defects to the thin film.

#### IV. CONCLUSION

In summary, the a-IGTO TFTs with varied N-doping degree are obtained via a N plasma treatment approach. By rationally modulating the treating time, superior bias stress stability,  $V_{th}$  closer to 0 V, and almost no decline in mobility are simultaneously achieved in the a-IGTO TFTs with 6 min N plasma treatment. Specifically, the a-IGTO TFTs with 6 min N plasma treatment shows a  $V_{th}$  of  $-0.5$  V, a  $\mu_{FE}$  of  $15.8$  cm $^2$ /V $\cdot$ s, a SS of 235 mV/dec, and a small  $\Delta V_{th}$  for PBS (0.59 V), NBS ( $-0.62$  V), PBIS (0.81 V), and NBIS ( $-0.9$  V). The XPS results suggest that N plasma treatment could enhance the bias stress stability and control the  $V_{th}$  efficiently through passivating the defects such as  $V_O$  in the a-IGTO films. The LFN results indicate N-doping could decrease  $N_{it}$  and improve interface quality effectively. Therefore, the fabrication of N-doped a-IGTO TFTs has deep potential for low-power and high resolution flat-panel displays.
